Small Interfering RNAs (siRNAs) Can Knock Down Expression of Specific Proteins

RNA interference (RNAi) is a mechanism that cells use to suppress the expression of genes by either blocking translation of specific mRNAs through micro-RNAs (miRNAs) or degradation of specific mRNAs targeted by small interfering RNA (siRNA). The extensive use of miRNAs to regulate gene expression, especially during development, has been discussed in Chapter 8. Here we focus on the experimental use of siRNA technology to suppress the expression of genes in animal cells.

The discovery of the siRNA pathway arose from many different observations. For example, it was discovered in plants that recombinant expression of a gene could lead to the down-regulation of the target gene rather than the expected result of enhanced expression. A similar type of result was seen in the nematode *C. elegans*. Investigating this phenomenon, Andrew Fire and Craig Mello reported in 1998 that suppression could not be achieved by expressing either sense or antisense mRNA, but that it required expression of double-stranded RNA. Fire and Mello were awarded the Nobel Prize in Physiology or Medicine in 2006 for this discovery. Subsequent work in a number of systems showed that the double-stranded RNA has to be cleaved by a protein called Dicer to produce double-stranded fragments of 21 to 23 base pairs with a two-nucleotide overhang at each of the 3' ends. This double-stranded RNA is recognized by RISC (RNA-induced silencing complex), and one of the strands is

degraded by the associated argonaute protein. If the single-stranded siRNA sequence can base pair exactly with a target mRNA sequence, the argonaute protein–RNA complex cleaves the target mRNA, which is then degraded (Figure 9-38a). Although this system probably evolved as a defense mechanism against invading viruses, it has provided researchers with a very powerful tool to experimentally suppress the expression of particular genes and explore the resulting consequences. It has been used very effectively in many different systems, as we summarize below.

siRNA Knockdown in Cultured Cells Since the discovery in 2001 that treatment of cultured cells with siRNAs suppresses gene expression by degrading the target mRNA, siRNAs have been used in thousands of studies to suppress—or “knock down”—the levels of target proteins. To do this, researchers use computer programs to identify a ~21-base sequence in the mRNA that is unique to the target gene and has the characteristics optimal for siRNA. Double-stranded RNA is then synthesized and applied to cells in culture (Figure 9-38a). If effective, this will result in degradation of the specific mRNA, and no new target protein will be synthesized. However, the target protein is present at the beginning of the experiment, so the cells have to be able to grow to allow the endogenous protein to undergo its normal turnover as well as get diluted by cell division—this usually takes 24 to 72 hours. The level of the target protein is generally determined by immunoblotting (see Figure 3-39), and if significantly reduced, the phenotype of the cells is examined.

(a)

FIGURE 9-38 siRNA and DNA expressing shRNA can target the degradation of specific mRNAs in cultured cells. In the first step (1), a double-stranded siRNA that has homology to the target mRNA is introduced into cells by transfection. This double-stranded RNA is recognized by the RISC complex (2), which degrades one strand of the RNA and targets the mRNA with the homologous sequence (3). The target mRNA is cleaved (4) and degraded (5). In an alternative strategy, a DNA construct containing a sequence that when transcribed will form a hairpin is introduced into the cell (6). This DNA can either be introduced by transfection or carried in a virus particle. In either case, it is engineered to carry with it a drug-selectable marker (not shown) so that cells in which this DNA is integrated into the genome can be selected. When transcribed (7) and transported out of the

nucleus, the RNA hairpin becomes a substrate of the nuclease Dicer to generate the appropriate siRNA. (b) As an example of this technology, researchers wanted to examine the effects of knocking down a protein, called EBP50, that is a component of cell-surface microvilli (see Figure 17-21d). siRNAs were designed and their ability to knock down EBP50 in cultured cells assessed by doing an immunoblot with EBP50 antibodies and tubulin antibodies as a control. (c) They then examined the cells for microvilli by staining for the microvillar-specific protein ezrin. In these confocal sections at the top of the cell, untreated cells have abundant microvilli, whereas cells in which EBP50 has been knocked down only have a few microvilli around the cell periphery. [Parts (b) and (c) from Hanono et al., *J. Cell Biol.* **175**:803.]

FIGURE 9-39 RNAi screens can explore the function of all the genes in the nematode *Caenorhabditis elegans*. The determination of the *C. elegans* genome sequence in 1998 revealed it contains about 20,000 protein-encoding genes. This information opened the possibility of using RNAi to knock down expression of each gene to explore what effect it would have. Today this is routinely done. The nematode can live by eating the bacterium *Escherichia coli*, and it is possible to express in the bacterium a long stretch of double-stranded RNA corresponding to a single nematode gene. Remarkably, when the nematode eats the bacteria, the double-stranded RNA enters the cells of the gut and is recognized by Dicer and processed into siRNAs that spread to almost all the cells in the animal. Therefore, researchers have made a library of *E. coli* strains each expressing double-stranded RNA

corresponding to a nematode gene. (a) In this approach, a specific *E. coli* strain is fed to larval nematodes **1** and the expression of the target gene is suppressed in the germ line. Because these nematodes are self-fertilizing hermaphrodites (having the reproductive organs of both sexes), it is not necessary to mate them but merely to let the adult worms lay eggs **2**. When these grow into adults, the effect of RNAi on the target gene can be assessed. (b) In this example, the researchers were screening for genes necessary for nuclear movement. They identified a gene called TAC-1, whose product is located at centrosomes and is necessary for the normal distribution of microtubules, as revealed by immunofluorescence microscopy with tubulin antibodies. [Part (b) from N. Le Bot et al., *Current Biology* **13**:1499 (2003).]

Suppression of gene expression by siRNAs has become a standard technique; an example is shown in Figure 9-38b and 9-38c, and many other examples can be found throughout this book.

An alternative strategy to knockdown protein expression is to introduce appropriate DNA constructs into cells that will generate siRNAs when they are transcribed (see Figure 9-38a). To achieve this, the target sequence is present as an inverted repeat in the DNA sequence. When transcribed, the mRNA will form a double-stranded short hairpin RNA (shRNA), which is recognized and cleaved by Dicer to generate siRNAs. This approach has the advantage that once the shRNA is expressed, the siRNAs are always made, resulting in permanent knockdown of the target protein. This will not work if the protein is essential, in which case treating cells with siRNAs is the method of choice. The DNA construct to express shRNAs can be introduced into cells by simple addition of the DNA under the

appropriate conditions that allow the cells to take it up or by use of viral vectors that more efficiently introduce the DNA.

Massive efforts are currently under way to explore the effects of knocking down expression of each gene in cultured cell lines and then examining the effects on specific pathways. This effort is in its infancy, so future refinements and analysis will provide a “systems biology” view of cell organization and function.

Genomic Screens Using siRNA in the Nematode *C. elegans*

When the annotated genome sequence of the nematode worm *Caenorhabditis elegans* was determined in 1998, this provided the first catalog of all the genes present in an animal. It also

FIGURE 9-40 RNAi screens can explore the function of all the genes in cultured cells. Cultured cells from the fruit fly *Drosophila melanogaster* can take up RNAi to inhibit the expression of specific genes. In this example, researchers wanted to identify genes that affected the mitotic spindle. 14,425 different double-stranded RNAs are arrayed in 96 well plates **1**. *Drosophila* cells are added to each well, the target gene is suppressed, and the cells are stained for microtubules and a component of the spindle pole. The cells are then examined in an automated microscope **2**. The images are then analyzed by a computer, and a gallery of images assembled **3**. A researcher then examines the images for those that have a consistent effect on spindle organization. (b) Various examples of aberrant spindles were recovered in this screen and stained for microtubules (green), a spindle pole component (red), and DNA (blue). [Parts (a) step 4 and part (b) from G. Goshima et al., 2007, *Science* **316**:417.]

provided the possibility to explore the function of each gene using RNAi to suppress expression of each individual gene. In fact, this nematode was the first animal in which a genomic RNAi screen was attempted. *C. elegans* can live by eating the bacterium *E. coli*. Remarkably, if the bacterium expresses a double-stranded RNA homologous to a nematode gene, when the bacteria are eaten, they are broken open and the RNA is absorbed through the intestine, then processed by Dicer to suppress expression of the target gene. Since there are about 20,000 different genes in the nematode, this many different *E. coli* strains were generated, each expressing double-stranded RNA targeted to a specific nematode gene. In a typical experiment to suppress expression of a single gene (Figure 9-39a), nematodes are grown on the bacteria expressing the specific double-stranded RNA, and this suppresses expression of the target gene in their embryos. After the adult nematodes have laid eggs, they are removed and the effect on the growing embryos is examined (Figure 9-39b).

Genomic Screens Using siRNA in Fruit Flies The fruit fly has about 14,000 protein-encoding genes, and techniques have

been developed to explore the consequence of using siRNA to suppress each of these in cultured fruit fly cells. With such a large number to be tested, automatic high-throughput approaches were developed (Figure 9-40a). For example, about 150 96 well plates are made, with each well containing one double-stranded RNA for a specific gene. Cells are added, and the double-stranded RNA is taken up and processed by Dicer into siRNAs, which then suppress expression of the target gene. The cells can then be examined for a specific phenotype. In the example shown in Figure 9-40b, the investigators explored the effect of gene suppression on cells arrested in mitosis. Since this is a morphological screen, they stained cells with appropriate markers and used a robotic microscope to take pictures and a computer program to analyze them. In this way they identified about 150 new genes whose products contribute to mitosis and are therefore excellent subjects for further in-depth studies.

Unlike in the nematode described above, it is not possible to suppress expression of genes by feeding fly larvae double-stranded RNA. However, it is possible to use RNAi for tissue-specific suppression. This is achieved by making a fly in which a specific hairpin RNA is expressed behind an upstream-

activating sequence (UAS) for the DNA-binding protein Gal4. In the absence of Gal4, the hairpin is not expressed, so no suppression occurs. However, if Gal4 is expressed behind a tissue-specific promoter, it will be expressed in that tissue, bind to the UAS, and drive expression of the hairpin RNA, which will be processed by Dicer into siRNAs and suppress the specific gene (Figure 9-41a). The system has been set up in this way so that it can be done on a genomic scale: 14,000 different fly lines have been made, each with the UAS to regulate expression of a hairpin specific for a target gene. When each of these flies is mated to a fly carrying the tissue-specific Gal4 gene, the

FIGURE 9-41 RNAi can be used to suppress genes in a tissue-specific manner in the fruit fly. Genetic approaches have been used to develop methods to suppress target gene expression in specific tissues. This involves making use of two large sets of flies. In the first set of about 14,000 different flies each designed to target one gene (set A), flies are generated in which a specific hairpin RNA for the target gene is under the control of an upstream activating sequence (UAS) for the transcriptional activator Gal4. In each of the second set of flies (set B), expression of GAL4 is controlled by a tissue-specific promoter. When a fly from set A is mated with a fly from set B, Gal4 will be expressed in one tissue and therefore the RNAi hairpin will be expressed and the gene silenced in this one tissue. (b) A wild-type fly eye (left), and one in which the *white* gene has been specifically suppressed in the eye (right). [Part (b) from N. Perrimon et al., 2010, *Cold Spring Harbor Perspect. Biol.* 2:a003640.]

effect of suppression of each gene in the genome can be tested in each tissue. This type of approach is currently ongoing, and exciting results are expected in the near future.

KEY CONCEPTS of Section 9.5

Perturbing Specific Cell Functions

- Genetic techniques have been critical in the analysis of complex cell biological pathways. Genetic approaches are now being extended and complemented by chemical screens and the use of RNAi technology.
- Large chemical libraries can be screened for compounds that target specific processes to study those processes and to identify new components.
- Treatment of cultured cells with appropriate siRNAs leads to the destruction of target mRNAs and hence “knock-down” of the encoded protein.
- With the availability of annotated genomes, RNAi screens can be used to explore the effect of suppressing expression of each individual gene in an organism. This has been achieved in the nematode worm and in cultured cells from the fruit fly.
- RNAi can be used to suppress expression of specific genes in a tissue-specific manner; this technique is currently being applied on a genomic scale in the fruit fly.

Perspectives for the Future

This chapter has introduced many aspects of technology currently used by cell biologists. Science is driven by the technology available, and with each development we can peer more deeply into the mysteries of life.

The ability to grow cells in culture was a tremendous advance in technology—it allowed researchers to examine and explore the inner workings of cells. Techniques in cell culture are still developing; for example, they are currently contributing to the exciting developments in stem-cell research (see Chapter 21). Although most studies have used flat dishes to grow these cells, in the body they form a three-dimensional structure. Major areas of research are now examining the functions of cells in three-dimensional environments and generating three-dimensional cell organizations, such as epithelial tubes, in supported culture systems.

The discovery and use of GFP and other fluorescent proteins has revolutionized cell biology. By tagging proteins with GFP and following their localization in live cells, it has become apparent that the cytoplasm of cells is far more dynamic than previously envisaged. Every year brings new technologies associated with fluorescent proteins; approaches such as FRAP, FRET, and TIRF have become widespread tools to explore the dynamics and molecular mechanisms of

proteins, either in vivo or in vitro. At the time of this writing, we are seeing a revolution in super-resolution microscopy, opening up the ability to localize molecules by light microscopy several times more accurately than was believed to be possible. Super-resolution microscopy can currently be done only on fixed samples; optimists believe it will soon be possible to achieve this level of resolution in living cells and thereby open up the possibility of watching dynamic processes at the molecular level. As these techniques develop, fewer people need to use electron microscopy, and so the expertise in this important area is waning.

RNAi has provided an awesome and unanticipated new technology to the arsenal of techniques available to cell and developmental biologists. The ability to perform genome-wide screens in both the nematode worm and fruit fly has made traditionally excellent genetic systems even more powerful. Coupling these technologies with visual screens opens up yet another dimension. Consider the following problem: which genes in the nematode affect the organization of a small subset of neurons? A few years ago, this would have been a technically challenging problem. Now it is possible to make a nematode in which just those neurons are marked with GFP and then subject them to a visual genomics RNAi screen to see which gene products are necessary for the normal morphology of those neurons. More and more imaginative approaches are being developed combining RNAi with visual and functional screens in both nematode worms and the fruit fly, permitting an ever-deepening understanding of life processes. In addition, efforts are currently under way to explore the effects of knocking down expression of each gene in cultured cell lines and then examining the effects on specific pathways. This effort is in its infancy, so future refinements and analysis will provide a systems biology view of cell organization and function.

Can RNAi technology be used in medicine? Could it be used to suppress expression of oncogenes in the treatment of cancer? The technological delivery problems are significant since the siRNA needs to be delivered to the right cells, remain stable in the patient, and be effective at knocking down the appropriate protein. Currently, at least a dozen clinical trials are testing the feasibility of this approach. If the technical hurdles can be overcome, RNAi might become a major class of therapeutic agent.

What new technologies will the next decade bring? In the last decade, RNAi and GFP have revolutionized cell biology. No doubt the next decade will bring about unexpected new developments, so we should be excited about what is to come.

Review the Concepts

- Both light and electron microscopy are commonly used to visualize cells, cell structures, and the location of specific molecules. Explain why a scientist may choose one or the other microscopy technique for use in research.
- The magnification possible with any type of microscope is an important property, but its resolution, the ability to distinguish between two very closely apposed objects, is even more critical. Describe why the resolving power of a microscope is more important for seeing finer details than its magnification. What is the formula to describe the resolution of a microscope lens and what are the limitations placed on the values in the formula?
- Why are chemical stains required for visualizing cells and tissues with the basic light microscope? What advantage do fluorescent dyes and fluorescence microscopy provide in comparison to the chemical dyes used to stain specimens for light microscopy? What advantages do confocal scanning microscopy and deconvolution microscopy provide in comparison to conventional fluorescence microscopy?
- In certain electron microscopy methods, the specimen is not directly imaged. How do these methods provide information about cellular structure, and what types of structures do they visualize? What limitation applies to most forms of electron microscopy?
- What is the difference between a cell strain, a cell line, and a clone?

6. Explain why the process of cell fusion is necessary to produce monoclonal antibodies used for research.
7. Much of what we know about cellular function depends on experiments utilizing specific cells and specific parts (e.g., organelles) of cells. What techniques do scientists commonly use to isolate cells and organelles from complex mixtures, and how do these techniques work?
8. Hoechst 33258 is a chemical dye that binds specifically to DNA in live cells, and when excited by UV light, it fluoresces in the visible spectrum. Name and describe one specific method, employing Hoechst 33258, an investigator would use to isolate fibroblasts in the G₂ phase of the cell cycle from those fibroblasts in interphase.
9. shRNAs and siRNAs can be used to successfully knock down the expression of any specific protein in a given cell line or organism. The utility of one over the other is debatable, but there are merits to using one for therapeutic applications in a living organism. Which of the two methods is likely to be more advantageous in the long-term and what is one of its limitations?

Analyze the Data

1. Mouse liver cells were homogenized and the homogenate subjected to equilibrium density-gradient centrifugation with sucrose gradients. Fractions obtained from these gradients were assayed for *marker molecules* (i.e., molecules that are limited to specific organelles). The results of these assays are shown in the figure. The marker molecules have the following functions: cytochrome oxidase is an enzyme involved in the process by which ATP is formed in the complete aerobic deg-

Curve A = cytochrome oxidase Curve D = acid phosphatase
 Curve B = ribosomal RNA Curve E = cytidylyl transferase
 Curve C = catalase Curve F = amino acid permease

radation of glucose or fatty acids; ribosomal RNA forms part of the protein-synthesizing ribosomes; catalase catalyzes decomposition of hydrogen peroxide; acid phosphatase hydrolyzes monophosphoric esters at acid pH; cytidylyl transferase is involved in phospholipid biosynthesis; and amino acid permease aids in transport of amino acids across membranes.

a. Name the marker molecule and give the number of the fraction that is *most* enriched for each of the following cell components: lysosomes; peroxisomes; mitochondria; plasma membrane; rough endoplasmic reticulum; smooth endoplasmic reticulum.

b. Is the rough endoplasmic reticulum more or less dense than the smooth endoplasmic reticulum? Why?

c. Describe an alternative approach by which you could identify which fraction was enriched for which organelle.

d. How would addition of a detergent to the homogenate, which disrupts membranes by solubilizing their lipid and protein components, affect the equilibrium density-gradient results?

2. The nematode worm *C. elegans* is amenable as a model for siRNA studies. In this experiment, adult nematodes are fed bacteria expressing a double-stranded RNA to suppress the expression of the *unc18* gene, whose mammalian homolog encodes a protein that participates in the integration of GLUT4 storage vesicles into the plasma membrane. Before evaluating the effects on the organism itself, it is necessary to use RT-PCR to analyze if the siRNA experiment worked. The samples are from embryos from five adults fed the bacteria, and the results are those following the RT-PCR using primers to amplify mRNA from the two different genes, *unc18* and *GLUT4*.

a. Of the embryos examined, which samples show that the adults successfully took up bacteria containing the double-stranded *unc18* RNA? What made you come to those conclusions?

b. Label which set of bands is the result of the amplification by the unc18 primers and which by the GLUT4 primers. Why was RT-PCR with GLUT4 primers used as the positive control? What does this tell you about the relationship between the knock down of the unc18 and GLUT4 mRNAs?

c. With antibodies against unc18, draw a representative Western blot showing the expected results from protein samples from each of these five samples.

d. To further investigate the relationship between the unc18 and GLUT4 proteins, the siRNA experiment is repeated, but in embryonic cells expressing a GFP-tagged GLUT4 protein. Draw a cell including its mitochondria, nucleus, and rough endoplasmic reticulum and show where, if using a laser scanning confocal microscope, the GFP fluorescence would localize in the cells expressing the unc18 siRNAs. Do not forget to draw the cell representing the control.

e. The ability of a protein to colocalize with another protein suggests but does not prove that the two physically interact with each other. Having each protein labeled, in this case unc18 to green fluorescent protein and GLUT4 to red fluorescent protein, provides the experimenter with reagents to tease apart the question of colocalization versus interaction. Using these reagents, describe one technique that would simply demonstrate unc18 colocalizes with GLUT4 and another technique that proves the two proteins interact physically.

Separating Organelles

H. Beaufay et al., 1964, *Biochemical Journal* 92:191

In the 1950s and 1960s, scientists used two techniques to study cell organelles: microscopy and fractionation. Christian de Duve was at the forefront of cell fractionation. In the early 1950s, he used centrifugation to distinguish a new organelle, the lysosome, from previously characterized fractions: the nucleus, the mitochondrial-rich fraction, and the microsomes. Soon thereafter, he used equilibrium-density centrifugation to uncover yet another organelle.

Background

Eukaryotic cells are highly organized and composed of cell structures known as organelles that perform specific functions. Although microscopy has allowed biologists to describe the location and appearance of various organelles, it is of limited use in uncovering an organelle's function. To do this, cell biologists have relied on a technique known as cell fractionation. Here cells are broken open and the cellular components are separated on the basis of size, mass, and density using a variety of centrifugation techniques. Scientists could then isolate and analyze cell components of different densities, called *fractions*. Using this method, biologists had divided the cell into four fractions: nuclei, mitochondrial-rich fraction, microsomes, and cell sap.

De Duve was a biochemist interested in the subcellular locations of metabolic enzymes. He had already completed a large body of work on the fractionation of liver cells, in which he had determined the subcellular location of numerous enzymes. By locating these enzymes in specific cell fractions, he could begin to elucidate the function of the organelle. He noted that his work was guided by two hypotheses: the "postulate of biochemical homogeneity" and "the postulate of single location." In short, these hypotheses propose that the entire composition of

a subcellular population will contain the same enzymes and that each enzyme is located at a discrete site within the cell. Armed with these hypotheses and the powerful tool of centrifugation, de Duve further subdivided the mitochondrial-rich fraction. First, he identified the light mitochondrial fraction, which is made up of hydrolytic enzymes that are now known to compose the lysosome. Then, in a series of experiments described here, he identified another discrete subcellular fraction, which he called the peroxisome, within the mitochondrial-rich fraction.

The Experiment

De Duve studied the distribution of enzymes in rat liver cells. Highly active in energy metabolism, the liver contains a number of useful enzymes to study. To look for the presence of various enzymes during the fractionation, de Duve relied on known tests, called enzyme assays, for enzyme activity. To retain maximum enzyme activity, he had to take precautions, which included performing all fractionation steps at 0 °C to reduce protease activity.

De Duve used rate-zonal centrifugation to separate cellular components by successive centrifugation steps. He removed the rat's liver and broke it apart by homogenization. The crude preparation of homogenized cells was then subjected to relatively low-speed centrifugation. This initial step separated the cell nucleus, which collects as sediment at the bottom of the tube, from the cytoplasmic extract, which remains in the supernatant. Next, de Duve further subdivided the cytoplasmic extract into heavy mitochondrial fraction, light mitochondrial fraction, and microsomal fraction. He accomplished separating the cytoplasm by employing successive centrifugation steps of increasing force. At each step he collected and stored the fractions for

subsequent enzyme analysis. Once the fractionation was complete, de Duve performed enzyme assays to determine the subcellular distribution of each enzyme. He then graphically plotted the distribution of the enzyme throughout the cell. As had been shown previously, the activity of cytochrome oxidase, an important enzyme in the electron-transfer system, was found primarily in the heavy mitochondrial fractions. The microsomal fraction was shown to contain another previously characterized enzyme, glucose-6-phosphatase. The light mitochondrial fraction, which is made up of the lysosome, showed the characteristic acid phosphatase activity. Unexpectedly, de Duve observed a fourth pattern when he assayed uricase activity. Rather than following the pattern of the reference enzymes, uricase activity was sharply concentrated within the light mitochondrial fraction. This sharp concentration, in contrast to the broad distribution, suggested to de Duve that the uricase might be secluded in another subcellular population separate from the lysosomal enzymes.

To test this theory, de Duve employed a technique known as equilibrium density-gradient centrifugation, which separates macromolecules on the basis of density. Equilibrium density-gradient centrifugation can be performed using a number of different gradients, including sucrose and glycerol. In addition, the gradient can be made up in either water or "heavy water," which contains the hydrogen isotope deuterium in place of hydrogen. In his experiment, de Duve separated the mitochondrial-rich fraction prepared by rate-zonal centrifugation in each of these different gradients (see Figure 9-35). If uricase were part of a separate subcellular compartment, it would separate from the lysosomal enzymes in each gradient tested. De Duve performed the fractionations in this series of gradients, then performed

FIGURE 1 Graphical representation of the enzyme analysis of products from a sucrose gradient. The mitochondrial-rich fraction was separated as depicted in Figure 9-35, and then enzyme assays were performed. The relative concentration of active enzyme is plotted on the y axis; the height in the tube is plotted on the x axis. The peak activities of cytochrome oxidase (*top*) and acid phosphatase (*bottom*) are observed near the top of the tube. The peak activity of uricase (*middle*) migrates to the bottom of the tube.

enzyme assays as before. In each case, he found uricase in a separate population than the lysosomal enzyme acid phosphatase and the mitochondrial enzyme cytochrome oxidase (Figure 1). By repeatedly observing uricase activity in a distinct fraction from the activity of the lysosomal and mitochondrial enzymes, de Duve concluded that uricase was part of a separate organelle. The experiment also showed that two other enzymes, catalase and D-amino acid oxidase, segregated into the same fractions as uricase. Because each of these enzymes either produced or used

hydrogen peroxide, de Duve proposed that this fraction represented an organelle responsible for the peroxide metabolism and dubbed it the peroxisome.

Discussion

De Duve's work on cellular fractionation provided an insight into the function of cell structures as he sought to map the location of known enzymes. Examining the inventory of enzymes in a given cell fraction gave him *clues* to its function. His careful work resulted in the uncovering of two organelles:

the lysosome and the **peroxisome**. His work also provided important clues to the organelles' function. The lysosome, where de Duve found so many potentially destructive enzymes, is now known to be an important site for degradation of biomolecules. The **peroxisome** has been shown to be the site of fatty acid and amino acid oxidation, reactions that produce a large amount of hydrogen peroxide. In 1974, de Duve received the Nobel Prize for Physiology or Medicine in recognition of his pioneering work.

Molecular model of a lipid bilayer with embedded membrane proteins. Integral membrane proteins have distinct exoplasmic, cytosolic, and membrane-spanning domains. Shown here are portions of the insulin receptor, which regulates cell metabolism. [Ramon Andrade 3Dciencia/ Science Photo Library.]

Membranes participate in many aspects of cell structure and function. The **plasma membrane** defines the cell and separates the inside from the outside. In eukaryotes, membranes also define the intracellular organelles such as the nucleus, mitochondrion, and lysosome. These biomembranes all have the same basic architecture—a phospholipid bilayer in which proteins are embedded (Figure 10-1). By preventing the unassisted movement of most water-soluble substances from one side of the membrane to the other, the phospholipid bilayer serves as a permeability barrier, helping to maintain the characteristic differences between the inside and outside of the cell or organelle; in turn, the embedded proteins endow the membrane with specific functions, such as regulated transport of substances from one side to the other. Each cellular membrane has its own set of proteins that allow it to carry out a multitude of different functions.

Prokaryotes, the simplest and smallest cells, are about 1–2 μm in length and are surrounded by a single plasma membrane; in most cases they contain no internal membrane-limited subcompartments (see Figure 1-11). However, this

Biomembrane Structure

single plasma membrane contains hundreds of different types of proteins that are integral to the function of the cell. Some of these proteins catalyze ATP synthesis and initiation of DNA replication, for instance. Others include the many types of **membrane transport proteins** that enable specific ions, sugars, amino acids, and vitamins to cross the otherwise impermeable phospholipid bilayer to enter the cell and that allow specific metabolic products to exit. **Receptors** in the plasma membrane are proteins that allow the cell to recognize chemical signals present in its environment and adjust its metabolism or pattern of gene expression in response.

Eukaryotes also have a plasma membrane studded with a multitude of proteins that perform a variety of functions, including membrane transport, cell signaling, and connecting cells into tissues. In addition, eukaryotic cells—which are generally much larger than prokaryotes—also have a variety of internal membrane-bound organelles (see Figure 9-32). Each organelle membrane has a unique complement of proteins that enable it to carry out its characteristic cellular functions, such as ATP generation (in mitochondria) and DNA

FIGURE 10-1 Fluid mosaic model of biomembranes. A bilayer of phospholipids ~3 nm thick provides the basic architecture of all cellular membranes; membrane proteins give each cellular membrane its unique set of functions. Individual phospholipids can move laterally and spin within the plane of the membrane, giving the membrane a fluidlike consistency similar to that of olive oil. Noncovalent interactions between phospholipids, and between phospholipids and proteins, lend strength and resilience to the membrane, while the hydrophobic core of the bilayer prevents the unassisted movement of water-soluble

substances from one side to the other. Integral (transmembrane) proteins span the bilayer and often form dimers and higher-order oligomers. Lipid-anchored proteins are tethered to one leaflet by a covalently attached hydrocarbon chain. Peripheral proteins associate with the membrane primarily by specific noncovalent interactions with integral proteins or membrane lipids. Proteins in the plasma membrane also make extensive contact with the cytoskeleton. [After D. Engelman, 2005, *Nature* **438**:578–580.]

synthesis (in the nucleus). Many plasma membrane proteins also bind components of the **cytoskeleton**, a dense network of protein filaments that crisscrosses the cytosol to provide mechanical support for cellular membranes, interactions that are essential for the cell to assume its specific shape and for many types of cell movements.

Despite playing a structural role in cells, membranes are not rigid structures. They can bend and flex in three dimensions while still maintaining their integrity, due in part to abundant noncovalent interactions that hold lipids and proteins together. Moreover, within the plane of the membrane, there is considerable mobility of individual lipids and proteins. According to the *fluid mosaic model* of biomembranes, first proposed by researchers in the 1970s, the lipid bilayer behaves in some respects like a two-dimensional fluid, with individual lipid molecules able to move past one another as well as spin in place. Such fluidity and flexibility not only allows organelles to assume their typical shapes, but also enables the dynamic

FIGURE 10-2 Eukaryotic cell membranes are dynamic structures.

property of membrane budding and fusion, such as occurs when viruses are released from an infected cell (Figure 10-2a) and when the internal cellular membranes of the Golgi complex bud into vesicles in the cytosol (Figure 10-2b) and then fuse with other membranes to transport their contents from one organelle to another (Chapter 14).

We begin our examination of biomembranes by considering their lipid components. These not only affect membrane shape and function but also help anchor proteins to the membrane, modify membrane protein activities, and transduce signals to the cytoplasm. We then consider the structure of membrane proteins. Many of these proteins have large segments that are embedded in the hydrocarbon core of the phospholipid bilayer, and we will focus on the principal classes of such membrane proteins. Finally, we consider how lipids such as phospholipids and cholesterol are synthesized in cells and distributed to the many membranes and organelles. Cholesterol is an essential component of the plasma membrane of all animal cells but is toxic to the organism if present in excess.

10.1 The Lipid Bilayer: Composition and Structural Organization

In Chapter 2 we learned that phospholipids are the principal building blocks of biomembranes. The most common phospholipids in membranes are the phosphoglycerides (see Figure 2-20), but as we will see in this chapter, there are multiple types of phospholipid. All phospholipids are **amphipathic** molecules—they consist of two segments with very different chemical properties: a fatty acid-based (fatty acyl) hydrocarbon “tail” that is **hydrophobic** and partitions away from water, and a polar “head group” that is strongly **hydrophilic**, or water loving, and tends to interact with water molecules. The interactions of phospholipids with each other and with water largely determine the structure of biomembranes.

Besides phospholipids, biomembranes contain smaller amounts of other amphipathic lipids, such as glycolipids and cholesterol, which contribute to membrane function in important ways. We first consider the structure and properties of pure phospholipid bilayers and then discuss the composition and behavior of natural cell membranes. We will see how the precise lipid composition of a given membrane influences its physical properties.

Phospholipids Spontaneously Form Bilayers

The amphipathic nature of phospholipids, which governs their interactions, is critical to the structure of biomembranes. When a suspension of phospholipids is mechanically dispersed in aqueous solution, the phospholipids aggregate into one of three forms: spherical **micelles** and **liposomes**, or sheetlike **phospholipid bilayers**, which are two molecules thick (Figure 10-3). The type of structure formed by pure phospholipids or

FIGURE 10-3 The bilayer structure of biomembranes. (a) Electron micrograph of a thin section through an erythrocyte membrane stained with osmium tetroxide. The characteristic “railroad track” appearance of the membrane indicates the presence of two polar layers, consistent with the bilayer structure of phospholipid membranes. (b) Schematic interpretation of the phospholipid bilayer in which polar groups face outward to shield the hydrophobic fatty acyl tails from water. The hydrophobic effect and van der Waals interactions between the fatty acyl tails drive the assembly of the bilayer (Chapter 2). (c) Cross-sectional views of two other structures formed by dispersal of phospholipids in water. A spherical micelle has a hydrophobic interior composed entirely of fatty acyl chains; a spherical liposome consists of a phospholipid bilayer surrounding an aqueous center.

[Part (a) courtesy of J. D. Robertson.]

a mixture of phospholipids depends on several factors, including the length of the fatty acyl chains in the hydrophobic tail, their degree of saturation (i.e., the number of C—C and C=C bonds), and temperature. In all three structures, the hydrophobic effect causes the fatty acyl chains to aggregate and

exclude water molecules from the “core.” Micelles are rarely formed from natural phospholipids, whose fatty acyl chains generally are too bulky to fit into the interior of a micelle. However, micelles are formed if one of the two fatty acyl chains that make up the tail of a phospholipid is removed by hydrolysis, forming a lysophospholipid, as occurs upon treatment with the enzyme phospholipase. In aqueous solution, common detergents and soaps form micelles that behave like the balls in tiny ball bearings, thus giving soap solutions their slippery feel and lubricating properties.

Phospholipids of the composition present in cells spontaneously form symmetric phospholipid bilayers. Each phospholipid layer in this lamellar structure is called a *leaflet*. The hydrophobic fatty acyl chains in each leaflet minimize their contact with water by aligning themselves tightly together in the center of the bilayer, forming a hydrophobic core that is about 3–4 nm thick (Figure 10-3b). The close packing of these nonpolar tails is stabilized by van der Waals interactions between the hydrocarbon chains. Ionic and hydrogen bonds stabilize the interactions of the phospholipid polar head groups with one another and with water. Electron microscopy of thin membrane sections of cells stained with osmium tetroxide, which binds strongly to the polar head groups of phospholipids, reveals the bilayer structure (Figure 10-3a). A cross section of a single membrane stained with osmium tetroxide looks like a railroad track: two thin dark lines (the stained head group complexes) with a uniform light space of about 2 nm between them (the hydrophobic tails).

A phospholipid bilayer can be of almost unlimited size—from micrometers (μm) to millimeters (mm) in length or width—and can contain tens of millions of phospholipid molecules. The phospholipid bilayer is the basic structural unit of nearly all biological membranes. Its hydrophobic core prevents most water-soluble substances from crossing from one side of the membrane to the other. Although biomembranes contain other molecules (e.g., cholesterol, glycolipids, proteins), it is the phospholipid bilayer that separates two aqueous solutions and acts as a permeability barrier. The lipid bilayer thus defines cellular compartments and allows a separation of the cell’s interior from the outside world.

Phospholipid Bilayers Form a Sealed Compartment Surrounding an Internal Aqueous Space

Phospholipid bilayers can be generated in the laboratory by simple means, using either chemically pure phospholipids or lipid mixtures of the composition found in cell membranes (Figure 10-4). Such synthetic bilayers possess three important properties. First, they are virtually impermeable to water-soluble (hydrophilic) solutes, which do not readily diffuse across the bilayer. This includes salts, sugars, and most other small hydrophilic molecules—including water itself. The second property of the bilayer is its stability. Hydrophobic and van der Waals interactions between the fatty acyl chains maintain the integrity of the interior of the bilayer structure.

EXPERIMENTAL FIGURE 10-4 Formation and study of pure phospholipid bilayers. (Top) A preparation of biological membranes is treated with an organic solvent, such as a mixture of chloroform and methanol (3:1), which selectively solubilizes the phospholipids and cholesterol. Proteins and carbohydrates remain in an insoluble residue. The solvent is removed by evaporation. (Bottom left) If the lipids are mechanically dispersed in water, they spontaneously form a liposome, shown in cross section, with an internal aqueous compartment. (Bottom right) A planar bilayer, also shown in cross section, can form over a small hole in a partition separating two aqueous phases; such a system can be used to study the physical properties of bilayers, such as their permeability to solutes.

Even though the exterior aqueous environment can vary widely in ionic strength and pH, the bilayer has the strength to retain its characteristic architecture. Third, all phospholipid bilayers can spontaneously form sealed closed compartments where the aqueous space on the inside is separated from that on the outside. An “edge” of a phospholipid bilayer, as depicted in Figure 10-3b, with the hydrocarbon core of the bilayer exposed to an aqueous solution, is unstable; the

FIGURE 10-5 The faces of cellular membranes. The plasma membrane, a single bilayer membrane, encloses the cell. In this highly schematic representation, internal cytosol (tan) and external environment (white) define the cytosolic (red) and exoplasmic (gray) faces of the bilayer. Vesicles and some organelles have a single membrane and their internal aqueous space (white) is topologically equivalent to the outside of the cell. Three organelles—the nucleus, mitochondrion, and chloroplast (which is not shown)—are enclosed by two membranes separated by a small intermembrane space. The exoplasmic faces of the inner and outer membranes around these organelles border the intermembrane space between them. For simplicity, the hydrophobic membrane interior is not indicated in this diagram.

exposed fatty acyl side chains would be in an energetically much more stable state if they were not adjacent to water molecules but surrounded by other fatty acyl chains (hydrophobic effect; Chapter 2). Thus in aqueous solution, sheets of phospholipid bilayers spontaneously seal their edges, forming a spherical bilayer that encloses an aqueous central compartment. The liposome depicted in Figure 10-3c is an example of such a structure viewed in cross section.

This physical chemical property of a phospholipid bilayer has important implications for cellular membranes: no membrane in a cell can have an “edge” with exposed hydrocarbon fatty acyl chains. All membranes form closed com-

partments, similar in basic architecture to liposomes. Because all cellular membranes enclose an entire cell or an internal compartment, they have an *internal face* (the surface oriented toward the interior of the compartment) and an *external face* (the surface presented to the environment). More commonly, we designate the two surfaces of a cellular membrane as the *cytosolic face* and the *exoplasmic face*. This nomenclature is useful in highlighting the topological equivalence of the faces in different membranes, as diagrammed in Figures 10-5 and 10-6. For example, the exoplasmic face of the plasma membrane is directed away from the cytosol, toward the extracellular space or external environment, and defines the outer limit of the cell. The cytosolic face of the plasma membrane faces the cytosol. Similarly for organelles and vesicles surrounded by a single membrane, the cytosolic

FIGURE 10-6 Faces of cellular membranes are conserved during membrane budding and fusion. Red membrane surfaces are cytosolic faces; gray are exoplasmic faces. During endocytosis a segment of the plasma membrane buds inward toward the cytosol and eventually pinches off a separate vesicle. During this process the cytosolic face of the plasma membrane remains facing the cytosol and the exoplasmic face of the new vesicle membrane faces the vesicle lumen. During exocytosis an intracellular vesicle fuses with the plasma membrane, and the lumen of the vesicle (exoplasmic face) connects with the extracellular medium. Proteins that span the membrane retain their asymmetric orientation during vesicle budding and fusion; in particular the same segment always faces the cytosol.

face faces the cytosol. The exoplasmic face is always directed away from the cytosol and in this case is on the inside of the organelle in contact with the internal aqueous space, or **lumen**. The lumen of these vesicles is topologically equivalent to the extracellular space, a concept most easily understood for vesicles that arise by invagination (endocytosis) of the plasma membrane. The external face of the plasma membrane becomes the internal face of the vesicle membrane, while in the vesicle the cytosolic face of the plasma membrane still faces the cytosol (Figure 10-6).

Three organelles—the nucleus, mitochondrion, and chloroplast—are surrounded not by a single membrane, but by two. The exoplasmic surface of each membrane faces the space between the two membranes. This can perhaps best be understood by reference to the *endosymbiont hypothesis*, discussed in Chapter 6, which posits that mitochondria and chloroplasts arose early in the evolution of eukaryotic cells by the engulfment of bacteria capable of oxidative phosphorylation or photosynthesis, respectively (see Figure 6-20).

Natural membranes from different cell types exhibit a variety of shapes, which complement a cell's function. The smooth, flexible surface of the erythrocyte plasma membrane allows the cell to squeeze through narrow blood capillaries (Figure 10-7a). Some cells have a long, slender extension of the plasma membrane, called a **cilium** or **flagellum**, which beats in a whiplike manner (Figure 10-7b). This motion causes fluid to flow across the surface of a sheet of cells, or a sperm cell to swim toward an egg. The differing shapes and properties of biomembranes raise a key question in cell biology, namely how the composition of biological membranes is regulated to establish and maintain the identity of the different membrane structures and membrane-delimited compartments. We return to this question in Section 10.3 and in Chapter 14.

Biomembranes Contain Three Principal Classes of Lipids

The term *phospholipid* is a somewhat generic term, encompassing multiple distinct molecules from multiple classes. It refers to any amphipathic lipid with a phosphate-based head group and a two-pronged hydrophobic tail. A typical biomembrane actually contains three classes of amphipathic lipids: phosphoglycerides, sphingolipids, and sterols, which differ in their chemical structures, abundance, and functions in the membrane (Figure 10-8). While all phosphoglycerides are phospholipids, only certain sphingolipids are, and no sterols are.

Phosphoglycerides, the most abundant class of phospholipids in most membranes, are derivatives of glycerol 3-phosphate (see Figure 10-8a). A typical phosphoglyceride molecule consists of a hydrophobic tail composed of two fatty acid-based (acyl) chains esterified to the two hydroxyl groups in glycerol phosphate and a polar head group attached to the phosphate group. The two fatty acyl chains may differ in the number of carbons that they contain (commonly 16 or 18) and their degree of saturation (0, 1, or 2 double bonds). A phosphoglyceride is classified according to the nature of its head group. In phosphatidylcholines, the most abundant phospho-

FIGURE 10-7 Variation in biomembranes in different cell types.

lipids in the plasma membrane, the head group consists of choline, a positively charged alcohol, esterified to the negatively charged phosphate. In other phosphoglycerides, an OH-containing molecule such as ethanolamine, serine, or the sugar derivative inositol is linked to the phosphate group. The negatively charged phosphate group and the positively charged groups or hydroxyl groups on the head group interact strongly with water. At neutral pH, some phosphoglycerides (e.g., phosphatidylcholine and phosphatidylethanolamine) carry no net electric charge, whereas others (e.g., phosphatidylinositol and phosphatidylserine) carry a single net negative charge. Nonetheless, the polar head groups in all these

FIGURE 10-8 Three classes of membrane lipids. (a) Most phosphoglycerides are derivatives of glycerol 3-phosphate (red), which contains two esterified fatty acyl chains that constitute the hydrophobic "tail" and a polar "head group" esterified to the phosphate. The fatty acids can vary in length and be saturated (no double bonds) or unsaturated (one, two, or three double bonds). In phosphatidylcholine (PC), the head group is choline. Also shown are the molecules attached to the phosphate group in three other common phosphoglycerides: phosphatidylethanolamine (PE), phosphatidylserine (PS), and phosphatidylinositol (PI). Plasmalogens contain one fatty acyl chain attached to glycerol by an ester linkage and one attached by an ether linkage; these contain similar head groups as other phosphoglycerides. (b) Sphingolipids are derivatives of sphingosine (red), an amino alcohol with a long hydrocarbon chain. Various fatty acyl chains are connected

to sphingosine by an amide bond. The sphingomyelins (SM), which contain a phosphocholine head group, are phospholipids. Other sphingolipids are glycolipids in which a single sugar residue or branched oligosaccharide is attached to the sphingosine backbone. For instance, the simple glycolipid glucosylceramide (GlcCer) has a glucose head group. (c) The major sterols in animals (cholesterol), fungi (ergosterol), and plants (stigmasterol) differ slightly in structure, but all serve as key components of cellular membranes. The basic structure of sterols is a four-ring hydrocarbon (yellow). Like other membrane lipids, sterols are amphipathic. The single hydroxyl group is equivalent to the polar head group in other lipids; the conjugated ring and short hydrocarbon chain form the hydrophobic tail. [See H. Sprong et al., 2001, *Nature Rev. Mol. Cell Biol.* 2:504.]

phospholipids can pack together into the characteristic bilayer structure. When phospholipases act on phosphoglycerides, they produce lysophospholipids, which lack one of the two acyl chains. Lysophospholipids are not only important signaling molecules, released from cells and recognized by specific receptors; their presence can also affect the physical properties of the membranes in which they reside.

The *plasmalogens* are a group of phosphoglycerides that contain one fatty acyl chain attached to carbon 2 of glycerol by an ester linkage and one long hydrocarbon chain attached to carbon 1 of glycerol by an ether (C—O—C) rather than an ester linkage. Plasmalogens are particularly abundant in human brain and heart tissue. The greater chemical stability of the ether linkage in plasmalogens, compared to the ester linkage, or the subtle differences in their three-dimensional structure compared with that of other phosphoglycerides may have as yet unrecognized physiologic significance.

A second class of membrane lipid is the **sphingolipids**. All of these compounds are derived from sphingosine, an amino alcohol with a long hydrocarbon chain, and contain a long-chain fatty acid attached in amide linkage to the sphingosine amino group (see Figure 10-8b). Like phosphoglycerides, some sphingolipids have a phosphate-based polar head group. In sphingomyelin, the most abundant sphingolipid, phosphocholine is attached to the terminal hydroxyl group of sphingosine (see Figure 10-8b, SM). Thus sphingomyelin is a phospholipid, and its overall structure is quite similar to that of phosphatidylcholine. Sphingomyelins are similar in shape to phosphoglycerides and can form mixed bilayers with them. Other sphingolipids are amphipathic **glycolipids** whose polar head groups are sugars that are not linked via a phosphate group (and so technically are not phospholipids). Glucosylcerebroside, the simplest glycosphingolipid, contains a single glucose unit attached to sphingosine. In the complex glycosphingolipids called **gangliosides**, one or two branched sugar chains (oligosaccharides) containing sialic acid groups are attached to sphingosine. Glycolipids constitute 2–10 percent of the total lipid in plasma membranes; they are most abundant in nervous tissue.

Cholesterol and its analogs constitute the third important class of membrane lipids, the **sterols**. The basic structure of sterols is a four-ring isoprenoid-based hydrocarbon. The structures of the principal yeast sterol (ergosterol) and plant phytosterols (e.g., stigmasterol) differ slightly from that of cholesterol, the major animal sterol (see Figure 10-8c). The small differences in the biosynthetic pathways and structures of fungal and animal sterols are the basis of most antifungal drugs currently in use. Cholesterol, like the two other sterols, has a hydroxyl substituent on one ring. Although cholesterol is almost entirely hydrocarbon in composition, it is amphipathic because its hydroxyl group can interact with water. Because it lacks a phosphate-based head group, it is not a phospholipid. Cholesterol is especially abundant in the plasma membranes of mammalian cells but is absent from most prokaryotic and all plant cells. As much as 30–50 percent of the lipids in plant plasma membranes consists of certain sterols unique to plants. Between 50 and 90 percent of

the cholesterol in most mammalian cells is present in the plasma membrane and associated vesicles. Cholesterol and other sterols are too hydrophobic to form a bilayer structure on their own. Instead, at concentrations found in natural membranes, these sterols must intercalate between phospholipid molecules to be incorporated into biomembranes. When so intercalated, sterols provide structural support to membranes, preventing too close a packing of the phospholipids' acyl chains to maintain a significant measure of membrane fluidity, and at the same time conferring the necessary rigidity required for mechanical support. Some of these effects can be highly local, as in the case of lipid rafts, discussed below.

In addition to its structural role in membranes, cholesterol is the precursor for several important bioactive molecules. They include *bile acids*, which are made in the liver and help emulsify dietary fats for digestion and absorption in the intestines; steroid hormones produced by endocrine cells (e.g., adrenal gland, ovary, testes); and vitamin D produced in the skin and kidneys. Another critical function of cholesterol is its covalent addition to Hedgehog protein, a key signaling molecule in embryonic development (Chapter 16).

Most Lipids and Many Proteins Are Laterally Mobile in Biomembranes

In the two-dimensional plane of a bilayer, thermal motion permits lipid molecules to rotate freely around their long axes and to diffuse laterally within each leaflet. Because such movements are lateral or rotational, the fatty acyl chains

FIGURE 10-9 Gel and fluid forms of the phospholipid bilayer.

(Top) Depiction of gel-to-fluid transition. Phospholipids with long saturated fatty acyl chains tend to assemble into a highly ordered, gel-like bilayer in which there is little overlap of the nonpolar tails in the two leaflets. Heat disorders the nonpolar tails and induces a transition from a gel to a fluid within a temperature range of only a few degrees. As the chains become disordered, the bilayer also decreases in thickness. (Bottom) Molecular models of phospholipid monolayers in gel and fluid states, as determined by molecular dynamics calculations. [Bottom based on H. Heller et al., 1993, *J. Phys. Chem.* **97**:8343.]

remain in the hydrophobic interior of the bilayer. In both natural and artificial membranes, a typical lipid molecule exchanges places with its neighbors in a leaflet about 10^7 times per second and diffuses several micrometers per second at 37°C . These diffusion rates indicate that the bilayer is 100 times more viscous than water—about the same as the viscosity of olive oil. Even though lipids diffuse more slowly in the bilayer than in an aqueous solvent, a membrane lipid could diffuse the length of a typical bacterial cell ($1\ \mu\text{m}$) in only 1 second and the length of an animal cell in about 20 seconds. When artificial pure phospholipid membranes are cooled below 37°C , the lipids can undergo a *phase transition* from a liquidlike (fluid) state to a gel-like (semisolid) state, analogous to the liquid-solid transition when liquid water freezes (Figure 10-9). Below the phase-transition temperature, the rate of diffusion of the lipids drops precipitously. At usual physiologic temperatures, the hydrophobic interior of natural membranes generally has a low viscosity and a fluidlike consistency, in contrast to the gel-like consistency observed at lower temperatures.

In pure membrane bilayers (i.e., in the absence of protein), phospholipids and sphingolipids rotate and move laterally, but they do not spontaneously migrate, or flip-flop, from one leaflet to the other. The energetic barrier is too high; migration would require moving the polar head group from its aqueous environment through the hydrocarbon core of the bilayer to the aqueous solution on the other side. Special membrane proteins discussed in Chapter 11 are required to flip membrane lipids and other polar molecules from one leaflet to the other.

The lateral movements of specific plasma-membrane proteins and lipids can be quantified by a technique called *fluorescence recovery after photobleaching (FRAP)*. Phospholipids containing a fluorescent substituent are used to monitor lipid movement. For proteins, a fragment of a monoclonal antibody that is specific for the exoplasmic domain of the desired protein and that has only a single antigen-binding site is tagged with a fluorescent dye. With this method, described in Figure 10-10, the rate at which membrane molecules move—the diffusion coefficient—can be

EXPERIMENTAL FIGURE 10-10 Fluorescence recovery after photobleaching (FRAP) experiments can quantify the lateral movement of proteins and lipids within the plasma membrane.

(a) Experimental protocol. Step 1 Cells are first labeled with a fluorescent reagent that binds uniformly to a specific membrane lipid or protein. Step 2 A laser light is then focused on a small area of the surface, irreversibly bleaching the bound reagent and thus reducing the fluorescence in the illuminated area. Step 3 In time, the fluorescence of the bleached patch increases as unbleached fluorescent surface molecules diffuse into it and bleached ones diffuse outward. The extent of recovery of fluorescence in the bleached patch is

proportional to the fraction of labeled molecules that are mobile in the membrane. (b) Results of a FRAP experiment with human hepatoma cells treated with a fluorescent antibody specific for the asialoglycoprotein receptor protein. The finding that 50 percent of the fluorescence returned to the bleached area indicates that 50 percent of the receptor molecules in the illuminated membrane patch were mobile and 50 percent were immobile. Because the rate of fluorescence recovery is proportional to the rate at which labeled molecules move into the bleached region, the diffusion coefficient of a protein or lipid in the membrane can be calculated from such data. [See Y. I. Henis et al., 1990, *J. Cell Biol.* 111:1409.]

determined, as well as the proportion of the molecules that are laterally mobile.

The results of FRAP studies with fluorescence-labeled phospholipids have shown that in fibroblast plasma membranes, all the phospholipids are freely mobile over distances of about 0.5 μm, but most cannot diffuse over much longer distances. These findings suggest that protein-rich regions of the plasma membrane about 1 μm in diameter separate lipid-rich regions containing the bulk of the membrane phospholipid. Phospholipids are free to diffuse within such regions but not from one lipid-rich region to an adjacent one. Furthermore, the rate of lateral diffusion of lipids in the plasma membrane is nearly an order of magnitude slower than in pure phospholipid bilayers: diffusion constants of 10⁻⁸ cm²/s and 10⁻⁷ cm²/s are characteristic of the plasma membrane and a lipid bilayer, respectively. This difference suggests that lipids may be tightly but not irreversibly bound to certain integral proteins in some membranes, as indeed has recently been demonstrated (see discussion of annular phospholipids, below).

Lipid Composition Influences the Physical Properties of Membranes

A typical cell contains many different types of membranes, each with unique properties derived from its particular mix of lipids and proteins. The data in Table 10-1 illustrate the variation in lipid composition in different biomembranes. Several phenomena contribute to these differences. For instance, the relative abundances of phosphoglycerides and sphingolipids differ between membranes in the endoplasmic

reticulum (ER), where phospholipids are synthesized, and the Golgi, where sphingolipids are synthesized. The proportion of sphingomyelin as a percentage of total membrane lipid phosphorus is about six times as high in Golgi membranes as it is in ER membranes. In other cases, the movement of membranes from one cellular compartment to another can selectively enrich certain membranes in lipids such as cholesterol. In responding to differing environments throughout an organism, different types of cells generate membranes with differing lipid compositions. In the cells that line the intestinal tract, for example, the membranes that face the harsh environment in which dietary nutrients are digested have a sphingolipid-to-phosphoglyceride-to-cholesterol ratio of 1:1:1 rather than the 0.5:1.5:1 ratio found in cells subject to less stress. The relatively high concentration of sphingolipid in this intestinal membrane may increase its stability because of extensive hydrogen bonding by the free —OH group in the sphingosine moiety (see Figure 10-8).

The degree of bilayer fluidity depends on the lipid composition, the structure of the phospholipid hydrophobic tails, and temperature. As already noted, van der Waals interactions and the hydrophobic effect cause the nonpolar tails of phospholipids to aggregate. Long, saturated fatty acyl chains have the greatest tendency to aggregate, packing tightly together into a gel-like state. Phospholipids with short fatty acyl chains, which have less surface area and therefore fewer van der Waals interactions, form more fluid bilayers. Likewise, the kinks in cis-unsaturated fatty acyl chains (Chapter 2) result in their forming less stable van der Waals interactions with other lipids, and hence more fluid bilayers, than do straight saturated chains, which can pack more tightly together.

TABLE 10-1 Major Lipid Components of Selected Biomembranes

Source/Location	Composition (mol %)			
	PC	PE + PS	SM	Cholesterol
Plasma membrane (human erythrocytes)	21	29	21	26
Myelin membrane (human neurons)	16	37	13	34
Plasma membrane (<i>E. coli</i>)	0	85	0	0
Endoplasmic reticulum membrane (rat)	54	26	5	7
Golgi membrane (rat)	45	20	13	13
Inner mitochondrial membrane (rat)	45	45	2	7
Outer mitochondrial membrane (rat)	34	46	2	11
Primary leaflet location	Exoplasmic	Cytosolic	Exoplasmic	Both

PC = phosphatidylcholine; PE = phosphatidylethanolamine; PS = phosphatidylserine; SM = sphingomyelin.

FIGURE 10-11 Effect of lipid composition on bilayer thickness and curvature. (a) A pure sphingomyelin (SM) bilayer is thicker than one formed from a phosphoglyceride such as phosphatidylcholine (PC). Cholesterol has a lipid-ordering effect on phosphoglyceride bilayers that increases their thickness, but it does not affect the thickness of the more-ordered SM bilayer. (b) Phospholipids such as PC have a cylindrical shape and form essentially flat monolayers, whereas those with smaller head groups such as phosphatidylethanolamine (PE) have a conical shape. (c) A bilayer enriched with PC in the exoplasmic leaflet and with PE in the cytosolic face, as in many plasma membranes, would have a natural curvature. [Adapted from H. Sprong et al., 2001, *Nature Rev. Mol. Cell Biol.* 2:504.]

Cholesterol is important in maintaining the appropriate fluidity of natural membranes, a property that appears to be essential for normal cell growth and reproduction. Cholesterol restricts the random movement of phospholipid head groups at the outer surfaces of the leaflets, but its effect on the movement of long phospholipid tails depends on concentration. At cholesterol concentrations present in the plasma membrane, the interaction of the steroid ring with the long hydrophobic tails of phospholipids tends to immobilize these lipids and thus decrease biomembrane fluidity. It is this property that can help organize the plasma membrane into discrete subdomains of unique lipid and protein composition. At lower cholesterol concentrations, however, the steroid ring separates and disperses phospholipid tails, causing the inner regions of the membrane to become slightly more fluid.

The lipid composition of a bilayer also influences its thickness, which in turn may influence the distribution of

other membrane components, such as proteins, in a particular membrane. It has been argued that relatively short trans-membrane segments of certain Golgi-resident enzymes (glycosyltransferases) are an adaptation to the lipid composition of the Golgi membrane and contribute to the retention of these enzymes in the Golgi apparatus. The results of biophysical studies on artificial membranes demonstrate that sphingomyelin associates into a more gel-like and thicker bilayer than phosphoglycerides do (Figure 10-11a). Cholesterol and other molecules that decrease membrane fluidity also increase membrane thickness. Because sphingomyelin tails are already optimally stabilized, the addition of cholesterol has no effect on the thickness of a sphingomyelin bilayer.

Another property dependent on the lipid composition of a bilayer is its curvature, which depends on the relative sizes of the polar head groups and nonpolar tails of its constituent phospholipids. Lipids with long tails and large head groups are cylindrical in shape; those with small head groups are cone shaped (Figure 10-11b). As a result, bilayers composed of cylindrical lipids are relatively flat, whereas those containing large numbers of cone-shaped lipids form curved bilayers (Figure 10-11c). This effect of lipid composition on bilayer curvature may play a role in the formation of highly curved membranes, such as sites of viral budding (see Figure 10-2) and formation of internal vesicles from the plasma membrane (see Figure 10-6), and in specialized stable membrane structures such as microvilli. Several proteins bind to the surface of phospholipid bilayers and cause the membrane to curve; such proteins are important in formation of transport vesicles that bud from a donor membrane (Chapter 14).

Lipid Composition Is Different in the Exoplasmic and Cytosolic Leaflets

A characteristic of all biomembranes is an asymmetry in lipid composition across the bilayer. Although most phospholipids are present in both membrane leaflets, some are commonly more abundant in one or the other leaflet. For instance, in plasma membranes from human erythrocytes and Madin Darby canine kidney (MDCK) cells grown in culture, almost all the sphingomyelin and phosphatidylcholine, both of which form less fluid bilayers, are found in the exoplasmic leaflet. In contrast, phosphatidylethanolamine, phosphatidylserine, and phosphatidylinositol, which form more fluid bilayers, are preferentially located in the cytosolic leaflet. Because phosphatidylserine and phosphatidylinositol carry a net negative charge, the stretch of amino acids on the cytoplasmic face of a single-pass membrane protein, in close proximity to the transmembrane segment, is often enriched in positively charged (Lys, Arg) residues, the “inside positive” rule. This segregation of lipids across the bilayer may influence membrane curvature (see Figure 10-11c). Unlike particular phospholipids, cholesterol is relatively evenly distributed in both leaflets of cellular membranes. The relative abundance of a particular phospholipid in the two leaflets of a plasma membrane can be determined experimentally on the basis of the susceptibility of phospholipids to hydrolysis

FIGURE 10-12 Specificity of phospholipases. Each type of phospholipase cleaves one of the susceptible bonds shown in red. The glycerol carbon atoms are indicated by small numbers. In intact cells, only phospholipids in the exoplasmic leaflet of the plasma membrane are cleaved by phospholipases in the surrounding medium. Phospholipase C, a cytosolic enzyme, cleaves certain phospholipids in the cytosolic leaflet of the plasma membrane.

by **phospholipases**, enzymes that cleave the ester bonds via which acyl chains and head groups are connected to the lipid molecule (Figure 10-12). When added to the external medium, phospholipases cannot cross the membrane, and thus they cleave off the head groups of only those lipids present in the exoplasmic face; phospholipids in the cytosolic leaflet are resistant to hydrolysis because the enzymes cannot penetrate to the cytosolic face of the plasma membrane.

How the asymmetric distribution of phospholipids in membrane leaflets arises is still unclear. As noted, in pure bilayers phospholipids do not spontaneously migrate, or flip-flop, from one leaflet to the other. In part, the asymmetry in phospholipid distribution may reflect where these lipids are synthesized in the endoplasmic reticulum and Golgi. Sphingomyelin is synthesized on the luminal (exoplasmic) face of the Golgi, which becomes the exoplasmic face of the plasma membrane. In contrast, phosphoglycerides are synthesized on the cytosolic face of the ER membrane, which is topologically equivalent to the cytosolic face of the plasma membrane (see Figure 10-5). Clearly, however, this explanation does not account for the preferential location of phosphatidylcholine (a phosphoglyceride) in the exoplasmic leaflet. Movement of this phosphoglyceride, and perhaps others, from one leaflet to the other in some natural membranes is most likely catalyzed by ATP-powered transport proteins called **flippases**, which are discussed in Chapter 11.

The preferential location of lipids on one face of the bilayer is necessary for a variety of membrane-based functions. For example, the head groups of all phosphorylated forms of phosphatidylinositol (see Figure 10-8; PI), an important source of second messengers, face the cytosol. Stimulation of many cell-surface receptors by their corresponding ligand

results in activation of the cytosolic enzyme phospholipase C, which can then hydrolyze the bond connecting the phosphoinositols to the diacylglycerol. As we will see in Chapter 15, both water-soluble phosphoinositols and membrane-embedded diacylglycerol participate in intracellular signaling pathways that affect many aspects of cellular metabolism. Phosphatidylserine also is normally most abundant in the cytosolic leaflet of the plasma membrane. In the initial stages of platelet stimulation by serum, phosphatidylserine is briefly translocated to the exoplasmic face, presumably by a flippase enzyme, where it activates enzymes participating in blood clotting. When cells die, lipid asymmetry is no longer maintained, and phosphatidylserine, normally enriched in the cytosolic leaflet, is increasingly found in the exoplasmic one. This increased exposure is detected by use of a labeled version of Annexin V, a protein that specifically binds to phosphatidylserine, to measure the onset of programmed cell death (apoptosis).

Cholesterol and Sphingolipids Cluster with Specific Proteins in Membrane Microdomains

Membrane lipids are not randomly distributed (evenly mixed) in each leaflet of a bilayer. One hint that lipids may be organized within the leaflets was the discovery that the lipids remaining after the extraction (solubilization) of plasma membranes with nonionic detergents such as Triton-X100 predominantly contain two species: cholesterol and sphingomyelin. Because these two lipids are found in more ordered, less fluid bilayers, researchers hypothesized that they form microdomains, termed **lipid rafts**, surrounded by other, more fluid phospholipids that are more readily extracted by nonionic detergents. (We discuss more fully the role of ionic and nonionic detergents in extracting membrane proteins in Section 10.2.)

Some biochemical and microscopic evidence supports the existence of lipid rafts, which in natural membranes are typically 50 nm in diameter. Rafts can be disrupted by methyl- β -cyclodextrin, which specifically extracts cholesterol out of membranes, or by antibiotics, such as filipin, that sequester cholesterol into aggregates within the membrane. Such findings indicate the importance of cholesterol in maintaining the integrity of these rafts. These raft fractions, defined by their insolubility in nonionic detergents, contain a subset of plasma membrane proteins, many of which are implicated in sensing extracellular signals and transmitting them into the cytosol. Because raft fractions are enriched in glycolipids, an important tool for microscopic visualization of raft-type structures in intact cells is the use of fluorescently labeled cholera toxin, a protein that specifically binds to certain gangliosides. By bringing many key proteins into close proximity and stabilizing their interactions, lipid rafts may facilitate signaling by cell-surface receptors and the subsequent activation of cytosolic events. However, much remains to be learned about the structure and biological function of lipid rafts.

Cells Store Excess Lipids in Lipid Droplets

Lipid droplets are vesicular structures, composed of triglycerides and cholesterol esters, that originate from the ER and serve a lipid-storage function. When a cell's supply of lipids exceeds the immediate need for membrane construction, excess lipids are relegated to these lipid droplets, readily visualized in living cells by staining with a lipophilic dye such as Congo red. Feeding cells with oleic acid, a type of fatty acid, enhances lipid droplet formation. Lipid droplets are not only storage compartments for triglycerides and cholesterol esters, but may also serve as platforms for storage of proteins targeted for degradation. The biogenesis of lipid droplets starts with delamination of the lipid bilayer of the ER, through insertion of triglycerides and cholesterol esters (Figure 10-13). The lipid "lens" continues to grow by insertion of more lipid, until finally a lipid droplet is hatched by scission from the ER. The resulting cytoplasmic droplet is thereby enwrapped by a phospholipid monolayer. The details of lipid droplet biogenesis as well as their functions remain to be defined more clearly.

FIGURE 10-13 Lipid droplets form by budding and scission from the ER membrane. Lipid droplet formation begins with the accumulation of cholesterol esters and triglycerides (yellow) within the hydrophobic core of the lipid bilayer. The resulting delamination of the two lipid monolayers causes a "lens" to form, the further growth of which creates a spherical droplet that is then released by scission at the neck. The newly formed droplet is surrounded by a lipid monolayer, derived from the cytosolic leaflet of the ER membrane.

KEY CONCEPTS of Section 10.1

The Lipid Bilayer: Composition and Structural Organization

- Membranes are crucial to cell structure and function. The eukaryotic cell is demarcated from the external environment by the plasma membrane and organized into membrane-limited internal compartments (organelles and vesicles).
- The phospholipid bilayer, the basic structural unit of all biomembranes, is a two-dimensional lipid sheet with hydrophilic faces and a hydrophobic core, which is impermeable to water-soluble molecules and ions; proteins embedded in the bilayer endow the membrane with specific functions (see Figure 10-1).
- The primary lipid components of biomembranes are phosphoglycerides, sphingolipids, and sterols such as cholesterol (see Figure 10-8). The term "phospholipid" applies to any amphipathic lipid molecule with a fatty acyl hydrocarbon tail and a phosphate-based polar head group.
- Phospholipids spontaneously form bilayers and sealed compartments surrounding an aqueous space (see Figure 10-3).
- As bilayers, all membranes have an internal (cytosolic) face and an external (exoplasmic) face (see Figure 10-5). Some organelles are surrounded by two, rather than one, membrane bilayer.
- Most lipids and many proteins are laterally mobile in biomembranes (see Figure 10-10). Membranes can undergo phase transitions from fluid- to gel-like states depending on the temperature and composition of the membrane (see Figure 10-9).
- Different cellular membranes vary in lipid composition (see Table 10-1). Phospholipids and sphingolipids are asymmetrically distributed in the two leaflets of the bilayer, whereas cholesterol is fairly evenly distributed in both leaflets.
- Natural biomembranes generally have a viscous consistency with fluidlike properties. In general, membrane fluidity is decreased by sphingolipids and cholesterol and increased by phosphoglycerides. The lipid composition of a membrane also influences its thickness and curvature (see Figure 10-11).
- Lipid rafts are microdomains containing cholesterol, sphingolipids, and certain membrane proteins that form in the plane of the bilayer. These lipid-protein aggregates might facilitate signaling by certain plasma membrane receptors.
- Lipid droplets are storage vesicles for lipids, originating in the ER (see Figure 10-13).

10.2 Membrane Proteins: Structure and Basic Functions

Membrane proteins are defined by their location within or at the surface of a phospholipid bilayer. Although every biological membrane has the same basic bilayer structure, the

proteins associated with a particular membrane are responsible for its distinctive activities. The kinds and amounts of proteins associated with biomembranes vary depending on cell type and subcellular location. For example, the inner mitochondrial membrane is 76 percent protein; the myelin membrane that surrounds nerve axons, only 18 percent. The high phospholipid content of myelin allows it to electrically insulate the nerve from its environment, as we discuss in Chapter 22. The importance of membrane proteins is evident from the finding that approximately a third of all yeast genes encode a membrane protein. The relative abundance of genes for membrane proteins is greater in multicellular organisms, in which membrane proteins have additional functions in cell adhesion.

The lipid bilayer presents a distinctive two-dimensional hydrophobic environment for membrane proteins. Some proteins contain segments that are embedded within the hydrophobic core of the phospholipid bilayer; other proteins are associated with the exoplasmic or cytosolic leaflet of the bilayer. Protein domains on the extracellular surface of the plasma membrane generally bind to extracellular molecules, including external signaling proteins, ions, and small metabolites (e.g., glucose, fatty acids), as well as proteins on other cells or in the external environment. Segments of proteins within the plasma membrane perform multiple functions, such as forming the channels and pores through which molecules and ions move into and out of cells. Intramembrane segments also serve to organize multiple membrane proteins into larger assemblies within the plane of the membrane. Domains lying along the cytosolic face of the plasma membrane have a wide range of functions, from anchoring cytoskeletal proteins to the membrane to triggering intracellular signaling pathways.

In many cases, the function of a membrane protein and the topology of its polypeptide chain in the membrane can be predicted on the basis of its similarity with other well-characterized proteins. In this section, we examine the characteristic structural features of membrane proteins and some of their basic functions. We will describe the structures of several proteins to help you get a feel for the way membrane proteins interact with membranes. More complete characterization of the properties of various types of membrane proteins is presented in later chapters that focus on their structures and activities in the context of their cellular functions.

Proteins Interact with Membranes in Three Different Ways

Membrane proteins can be classified into three categories—integral, lipid-anchored, and peripheral—on the basis of their position with respect to the membrane (see Figure 10-1). **Integral membrane proteins**, also called *transmembrane proteins*, span a phospholipid bilayer and comprise three segments. The cytosolic and exoplasmic domains have hydrophilic exterior surfaces that interact with the aqueous environment on the cytosolic and exoplasmic faces of the membrane. These domains resemble segments of other water-

soluble proteins in their amino acid composition and structure. In contrast, the membrane-spanning segments usually contain many hydrophobic amino acids whose side chains protrude outward and interact with the hydrophobic hydrocarbon core of the phospholipid bilayer. In all transmembrane proteins examined to date, the membrane-spanning domains consist of one or more α helices or of multiple β strands. We discussed the ribosomal synthesis and post-translational processing of soluble cytosolic proteins in Chapters 4 and 8; the process by which integral membrane proteins are inserted into membranes as part of their synthesis is discussed in Chapter 13.

Lipid-anchored membrane proteins are bound covalently to one or more lipid molecules. The hydrophobic segment of the attached lipid is embedded in one leaflet of the membrane and anchors the protein to the membrane. The polypeptide chain itself does not enter the phospholipid bilayer.

Peripheral membrane proteins do not directly contact the hydrophobic core of the phospholipid bilayer. Instead they are bound to the membrane either indirectly by interactions with integral or lipid-anchored membrane proteins or directly by interactions with lipid head groups. Peripheral proteins can be bound to either the cytosolic or the exoplasmic face of the plasma membrane. In addition to these proteins, which are closely associated with the bilayer, cytoskeletal filaments can be more loosely associated with the cytosolic face, usually through one or more peripheral (adapter) proteins. Such associations with the cytoskeleton provide support for various cellular membranes, helping to determine cell shape and mechanical properties, and play a role in the two-way communication between the cell interior and the exterior, as we learn in Chapter 17. Finally, peripheral proteins on the outer surface of the plasma membrane and the exoplasmic domains of integral membrane proteins are often attached to components of the extracellular matrix or to the cell wall surrounding bacterial and plant cells, providing a crucial interface between the cell and its environment.

Most Transmembrane Proteins Have Membrane-Spanning α Helices

Soluble proteins exhibit hundreds of distinct localized folded structures, or motifs (see Figure 3-9). In comparison, the repertoire of folded structures in the transmembrane domains of integral membrane proteins is quite limited, with the hydrophobic α helix predominating. Proteins containing membrane-spanning α -helical domains are stably embedded in membranes because of energetically favorable hydrophobic and van der Waals interactions of the hydrophobic side chains in the domain with specific lipids and probably also by ionic interactions with the polar head groups of the phospholipids.

A single α -helical domain is sufficient to incorporate an integral membrane protein into a membrane. However, many proteins have more than one transmembrane α helix. Typically, a membrane-embedded α helix is composed of a continuous segment of 20–25 hydrophobic (uncharged)

FIGURE 10-14 Structure of glycoporphin A, a typical single-pass transmembrane protein. (a) Diagram of dimeric glycoporphin showing major sequence features and its relation to the membrane. The single 23-residue membrane-spanning α helix in each monomer is composed of amino acids with hydrophobic (uncharged) side chains (red and green spheres). By binding negatively charged phospholipid head groups, the positively charged arginine and lysine residues (blue spheres) near the cytosolic side of the helix help anchor glycoporphin in the membrane. Both the extracellular and the cytosolic domains are rich in charged residues and polar uncharged residues; the extracellular

domain is heavily glycosylated, with the carbohydrate side chains (green diamonds) attached to specific serine, threonine, and asparagine residues. (b) Molecular model of the transmembrane domain of dimeric glycoporphin corresponding to residues 73–96. The hydrophobic side chains of the α helix in one monomer are shown in pink; those in the other monomer, in green. Residues depicted as space-filling structures participate in van der Waals interactions that stabilize the coiled-coil dimer. Note how the hydrophobic side chains project outward from the helix, toward what would be the surrounding fatty acyl chains. [Part (b) adapted from K. R. MacKenzie et al., 1997, *Science* **276**:131.]

amino acids (see Figure 2-14). The predicted length of such an α helix (3.75 nm) is just sufficient to span the hydrocarbon core of a phospholipid bilayer. In many membrane proteins, these helices are perpendicular to the plane of the membrane, whereas in others, the helices traverse the membrane at an oblique angle. The hydrophobic side chains protrude outward from the helix and form van der Waals interactions with the fatty acyl chains in the bilayer. In contrast, the hydrophilic amide peptide bonds are in the interior of the α helix (see Figure 3-4); each carbonyl ($\text{C}=\text{O}$) group forms a hydrogen bond with the amide hydrogen atom of the amino acid four residues toward the C-terminus of the helix. These polar groups are shielded from the hydrophobic interior of the membrane.

To help you get a better sense of the structures of proteins with α -helical domains, we will briefly discuss four different kinds of such proteins: glycoporphin A, G protein-coupled receptors, aquaporins (water/glycerol channels), and T-cell receptor for antigen.

Glycoporphin A, the major protein in the erythrocyte plasma membrane, is a representative *single-pass* transmem-

brane protein, which contains only one membrane-spanning α helix (Figure 10-14). The 23-residue membrane-spanning α helix is composed of amino acids with hydrophobic (uncharged) side chains, which interact with fatty acyl chains in the surrounding bilayer. In cells, glycoporphin A typically forms dimers: the transmembrane helix of one glycoporphin A polypeptide associates with the corresponding transmembrane helix in a second glycoporphin A to form a coiled-coil structure (Figure 10-14b). Such interactions of membrane-spanning α helices are a common mechanism for creating dimeric membrane proteins, and many membrane proteins form oligomers (two or more polypeptides bound together noncovalently) by interactions between their membrane-spanning helices.

A large and important group of integral proteins is defined by the presence of seven membrane-spanning α helices; this includes the large family of G protein-coupled cell-surface receptors discussed in Chapter 15, several of which have been crystallized. One such *multipass* transmembrane protein of known structure is bacteriorhodopsin, a protein found in the membrane of certain photosynthetic bacteria; it

FIGURE 10-15 Structural models of two multipass membrane proteins. (a) Bacteriorhodopsin, a photoreceptor in certain bacteria. The seven hydrophobic α helices in bacteriorhodopsin traverse the lipid bilayer roughly perpendicular to the plane of the membrane. A retinal molecule (black) covalently attached to one helix absorbs light. The large class of G protein-coupled receptors in eukaryotic cells also has seven membrane-spanning α helices; their three-dimensional structure is thought to be similar to that of bacteriorhodopsin. (b) Two views of the glycerol channel Glpf, rotated 180° with respect to each other along an axis perpendicular to the plane of the membrane. Note

several membrane-spanning α helices that are at oblique angles, the two helices that penetrate only halfway through the membrane (purple with yellow arrows), and one long membrane-spanning helix with a "break" or distortion in the middle (purple with yellow line). The glycerol molecule in the hydrophilic "core" is colored red. The structure was approximately positioned in the hydrocarbon core of the membrane by finding the most hydrophobic $3\text{-}\mu\text{m}$ slab of the protein perpendicular to the membrane plane. [Part (a) after H. Luecke et al., 1999, *J. Mol. Biol.* **291**:899. Part (b) after J. Bowie, 2005, *Nature* **438**:581–589, and D. Fu et al., 2000, *Science* **290**:481–486.]

illustrates the general structure of all these proteins (Figure 10-15a). Absorption of light by the retinal group covalently attached to this protein causes a conformational change in the protein that results in the pumping of protons from the cytosol across the bacterial membrane to the extracellular space. The proton concentration gradient thus generated across the membrane is used to synthesize ATP during photosynthesis (Chapter 12). In the high-resolution structure of bacteriorhodopsin the positions of all the individual amino acids, retinal, and the surrounding lipids are clearly defined. As might be expected, virtually all of the amino acids on the exterior of the membrane-spanning segments of bacteriorhodopsin are hydrophobic, permitting energetically favorable interactions with the hydrocarbon core of the surrounding lipid bilayer.

The **aquaporins** are a large family of highly conserved proteins that transport water, glycerol, and other hydrophilic molecules across biomembranes. They illustrate several aspects of the structure of multipass transmembrane proteins. Aquaporins are tetramers of four identical subunits. Each of the four subunits has six membrane-spanning α helices, some of which traverse the membrane at oblique angles rather than perpendicularly. Because the aquaporins have similar structures, we will focus on one, the glycerol channel Glpf, that has an especially well-defined structure determined by x-ray diffraction studies (Figure 10-15b). This

aquaporin has one long transmembrane helix with a bend in the middle, and more strikingly, there are two α helices that penetrate only *halfway* through the membrane. The N-termini of these helices face each other (yellow N's in the figure), and together they span the membrane at an oblique angle. Thus some membrane-embedded helices—and other, nonhelical, structures we will encounter later—do not traverse the entire bilayer. As we will see in Chapter 11, these short helices in aquaporins form part of the glycerol/water-selective pore in the middle of each subunit. This highlights the considerable diversity in the ways membrane-spanning α helices interact with the lipid bilayer and with other segments of the protein.

The specificity of phospholipid-protein interactions is evident from the structure of a different aquaporin, aquaporin 0 (Figure 10-16). Aquaporin 0 is the most abundant protein in the plasma membrane of the fiber cells that make up the bulk of the lens of the mammalian eye. Like other aquaporins, it is a tetramer of identical subunits. The protein's surface is not covered by a set of uniform binding sites for phospholipid molecules. Instead, fatty acyl side chains pack tightly against the irregular hydrophobic outer surface of the protein; these lipids are referred to as annular phospholipids, because they form a tight ring (annulus) of lipids that exchange less easily with bulk phospholipids in the bilayer. Some of the fatty acyl chains are straight, in the *all-trans* conformation (Chapter 2),

FIGURE 10-16 Annular phospholipids. Side view of the three-dimensional structure of one subunit of the lens-specific aquaporin 0 homotetramer, crystallized in the presence of the phospholipid dimyristoylphosphatidylcholine, a phospholipid with 14 carbon-saturated fatty acyl chains. Note the lipid molecules forming a bilayer shell around the protein. The protein is shown as a surface plot (the lighter background molecule). The lipid molecules are shown in space-fill format; the polar lipid head groups (grey and red) and the lipid fatty acyl chains (black and grey) form a bilayer with almost uniform thickness around the protein. Presumably, in the membrane, lipid fatty acyl chains will cover the whole of the hydrophobic surface of the protein; only the most ordered of the lipid molecules will be resolved in the crystallographic structure. [After A. Lee, 2005, *Nature* **438**:569–570, and T. Gonen et al., 2005, *Nature* **438**:633–688.]

whereas others are kinked in order to interact with bulky hydrophilic side chains on the surface of the protein. Some of the lipid head groups are parallel to the surface of the membrane, as is the case in purified phospholipid bilayers. Others, however, are oriented almost at right angles to the plane of the membrane. Thus there can be specific interactions between phospholipids and membrane-spanning proteins, and the function of many membrane proteins can be

affected by the specific types of phospholipid present in the bilayer.

In addition to the predominantly hydrophobic (uncharged) residues that serve to embed integral membrane proteins in the bilayer, many such α -helical transmembrane segments do contain polar and/or charged residues. Their amino acid side chains can be used to guide the assembly and stabilization of multimeric membrane proteins. The T-cell receptor for antigen is a case in point: it is composed of four separate dimers, the interactions of which are driven by charge-charge interactions between α helices at the appropriate “depth” in the hydrocarbon core of the lipid bilayer (Figure 10-17). The electrostatic attraction of positive and negative charges on each dimer helps the dimers to “find each other.” Thus charged residues in otherwise hydrophobic transmembrane segments can help guide assembly of multimeric membrane proteins.

FIGURE 10-17 Charged residues can orchestrate assembly of multimeric membrane proteins. The T-cell receptor (TCR) for antigen is composed of four separate dimers: an $\alpha\beta$ pair directly responsible for antigen recognition, and accessory subunits collectively referred to as the CD3 complex. These accessories include the γ , δ , ϵ , and ζ subunits. The ζ subunits form a disulfide-linked homodimer. The γ and δ subunits occur in complex with an ϵ subunit, to generate a $\gamma\epsilon$ and a $\delta\epsilon$ pair. The transmembrane segments of the TCR α and β chains each contain positively charged residues (blue). These allow recruitment of corresponding $\delta\epsilon$ and $\gamma\epsilon$ heterodimers, which carry negative charges (red) at the appropriate depth in the hydrophobic core of the bilayer. The ζ homodimer docks onto the charges in the TCR α chain (dark green), while the $\gamma\epsilon$ and $\delta\epsilon$ subunit pairs find their corresponding partners deeper down in the hydrophobic core on both the TCR α and TCR β chain (light green). Charged residues in otherwise nonpolar transmembrane segments can thus guide assembly of higher order structures. [After K.W. Wucherpfennig, et al., 2010, *Cold Spring Harb Perspect Biol*, **2**.]

Multiple β Strands in Porins Form Membrane-Spanning “Barrels”

The porins are a class of transmembrane proteins whose structure differs radically from that of other integral proteins based on α -helical transmembrane domains. Several types of porins are found in the outer membrane of gram-negative bacteria such as *E. coli* and in the outer membranes of mitochondria and chloroplasts. The outer membrane protects an intestinal bacterium from harmful agents (e.g., antibiotics, bile salts, and proteases) but permits the uptake and disposal of small hydrophilic molecules, including nutrients and waste products. Different types of porins in the outer membrane of an *E. coli* cell provide channels for the passage of specific types of disaccharides or other small molecules as well as of ions such as phosphate. The amino acid sequences of porins contain none of the long, continuous hydrophobic segments typical of integral proteins with α -helical membrane-spanning domains. Rather, it is the entire outer surface of the fully folded porin that displays its hydrophobic character to the hydrocarbon core of the lipid bilayer. X-ray crystallography shows that porins are trimers of identical subunits. In each subunit, 16 β strands form a sheet that twists into a barrel-shaped structure with a pore in the center (Figure 10-18). Unlike a typical water-soluble globular

FIGURE 10-18 Structural model of one subunit of OmpX, a porin found in the outer membrane of *E. coli*. All porins are trimeric transmembrane proteins. Each subunit is barrel shaped, with β strands forming the wall and a transmembrane pore in the center. A band of aliphatic (hydrophobic and noncyclic) side chains (yellow) and a border of aromatic (ring-containing) side chains (red) position the protein in the bilayer. [After G. E. Schulz, 2000, *Curr. Opin. Struc. Biol.* 10:443.]

protein, a porin has a hydrophilic interior and a hydrophobic exterior; in this sense, porins are inside out. In a porin monomer, the outward-facing side groups on each of the β strands are hydrophobic and form a nonpolar ribbonlike band that encircles the outside of the barrel. This hydrophobic band interacts with the fatty acyl groups of the membrane lipids or with other porin monomers. The side groups facing the inside of a porin monomer are predominantly hydrophilic; they line the pore through which small water-soluble molecules cross the membrane. (Note that the aquaporins discussed above, despite their name, are not porins and contain multiple transmembrane α helices.)

Covalently Attached Lipids Anchor Some Proteins to Membranes

In eukaryotic cells, covalently attached lipids can anchor some otherwise typically water-soluble proteins to one or the other leaflet of the membrane. In such lipid-anchored proteins, the lipid hydrocarbon chains are embedded in the bilayer, but the protein itself does not enter the bilayer. The lipid anchors used to anchor proteins to the cytosolic face are not used for the exoplasmic face and vice versa.

One group of cytosolic proteins are anchored to the cytosolic face of a membrane by a fatty acyl group (e.g., myristate or palmitate) covalently attached to an N-terminal glycine residue, a process called *acylation* (Figure 10-19a). Retention of such proteins at the membrane by the N-terminal acyl anchor may play an important role in a membrane-associated function. For example, v-Src, a mutant form of a cellular tyrosine kinase, induces abnormal cellular growth that can lead to cancer but does so only when it has a myristylated N-terminus.

A second group of cytosolic proteins are anchored to membranes by a hydrocarbon chain attached to a cysteine residue at or near the C-terminus, a process called *prenylation* (Figure 10-19b). Prenyl anchors are built from 5-carbon isoprene units, which, as detailed in the following section, are also used in the synthesis of cholesterol. In prenylation, a 15-carbon farnesyl or 20-carbon geranylgeranyl group is bound through a thioether bond to the $-SH$ group of a C-terminal cysteine residue of the protein. In some cases, a second geranylgeranyl group or a fatty acyl palmitate group is linked to a nearby cysteine residue. The additional hydrocarbon anchor is thought to reinforce the attachment of the protein to the membrane. For example, Ras, a GTPase superfamily protein that functions in intracellular signaling (Chapter 15), is recruited to the cytosolic face of the plasma membrane by such a double anchor. Rab proteins, which also belong to the GTPase superfamily, are similarly bound to the cytosolic surface of intracellular vesicles by prenyl anchors; these proteins are required for the fusion of vesicles with their target membranes (Chapter 14).

Some cell-surface proteins and specialized proteins with distinctive covalently attached polysaccharides called proteoglycans (Chapter 20) are bound to the exoplasmic face of the plasma membrane by a third type of anchor group, glycosylphosphatidylinositol (GPI). The exact structures of

FIGURE 10-19 Anchoring of plasma-membrane proteins to the bilayer by covalently linked hydrocarbon groups. (a) Cytosolic proteins such as v-Src are associated with the plasma membrane through a single fatty acyl chain attached to the N-terminal glycine (Gly) residue of the polypeptide. Myristate (C14) and palmitate (C16) are common acyl anchors. (b) Other cytosolic proteins (e.g., Ras and Rab proteins) are anchored to the membrane by prenylation of one or two cysteine (Cys) residues, at or near the C-terminus. The anchors are farnesyl (C15) and geranylgeranyl (C20) groups, both of which are unsaturated. (c) The lipid anchor on the exoplasmic surface of the plasma membrane is glycosylphosphatidylinositol (GPI). The phosphatidylinositol part (red) of this anchor contains two fatty acyl chains that extend into the bilayer. The phosphoethanolamine unit (purple) in the anchor links it to the protein. The two green hexagons represent sugar units, which vary in number, nature, and arrangement in different GPI anchors. The complete structure of a yeast GPI anchor is shown in Figure 13-15. [Adapted from H. Sprong et al., 2001, *Nature Rev. Mol. Cell Biol.* 2:504.]

GPI anchors vary greatly in different cell types, but they always contain phosphatidylinositol (PI), whose two fatty acyl chains extend into the lipid bilayer just like those of typical membrane phospholipids; phosphoethanolamine, which covalently links the anchor to the C-terminus of a protein; and several sugar residues (Figure 10-19c). Therefore GPI anchors are glycolipids. The GPI anchor is both necessary and sufficient for binding proteins to the membrane. For instance, treatment of cells with phospholipase C, which cleaves the phosphate-glycerol bond in phospholipids and in GPI anchors (see Figure 10-12), releases GPI-anchored proteins such as Thy-1 and placental alkaline phosphatase (PLAP) from the cell surface.

All Transmembrane Proteins and Glycolipids Are Asymmetrically Oriented in the Bilayer

Every type of transmembrane protein has a specific orientation, known as its *topology*, with respect to the membrane faces. Its cytosolic segments are always facing the cytoplasm,

and exoplasmic segments always face the opposite side of the membrane. This asymmetry in protein orientation confers different properties on the two membrane faces. The orientation of different types of transmembrane proteins is established during their synthesis, as we describe in Chapter 13. Membrane proteins have never been observed to flip-flop across a membrane; such movement, requiring a transient movement of hydrophilic amino acid residues through the hydrophobic interior of the membrane, would be energetically unfavorable. Accordingly, the asymmetric topology of a transmembrane protein, which is established during its biosynthetic insertion into a membrane, is maintained throughout the protein's lifetime. As Figure 10-6 shows, membrane proteins retain their asymmetric orientation in the membrane during membrane budding and fusion events; the same segment always faces the cytosol and the same segment is always exposed to the exoplasmic face. In proteins with multiple transmembrane segments (multipass or polytopic membrane proteins), orientation of individual transmembrane segments can be affected by changes in phospholipid composition.

Many transmembrane proteins contain carbohydrate chains covalently linked to serine, threonine, or asparagine side chains of the polypeptide. Such transmembrane **glycoproteins** are always oriented so that all carbohydrate chains are in the exoplasmic domain (see Figure 10-14 for the example of glycoporphin A). Likewise, glycolipids, in which a carbohydrate chain is attached to the glycerol or sphingosine backbone of a membrane lipid, are always located in the exoplasmic leaflet with the carbohydrate chain protruding from the membrane surface. The biosynthetic basis for the asymmetric glycosylation of proteins is described in Chapter 14. Both glycoproteins and glycolipids are especially abundant in the plasma membranes of eukaryotic cells and in the membranes of the intracellular compartments that establish the secretory and endocytic pathways; they are absent from the inner mitochondrial membrane, chloroplast lamellae, and several other intracellular membranes. Because the carbohydrate chains of glycoproteins and glycolipids in the plasma membrane extend into the extracellular space, they are available to interact with components of the extracellular matrix as well as **lectins** (proteins that bind specific sugars), growth factors, and antibodies.

One important consequence of such interactions is illustrated by the A, B, and O blood group antigens. These three structurally related oligosaccharide components of certain glycoproteins and glycolipids are expressed on the surfaces of human red blood cells and many other cell types (Figure 10-20). All humans have the enzymes for synthesizing O antigen. Persons with type A blood also have a glycosyltransferase enzyme that adds an extra modified monosaccharide called *N*-acetylgalactosamine to O antigen to form A antigen. Those with type B blood have a different transferase that adds an extra galactose to O antigen to form B antigen. People with both transferases produce both A and B antigen (AB blood type); those who lack these transferases produce O antigen only (O blood type).

FIGURE 10-20 Human ABO blood group antigens. These antigens are oligosaccharide chains covalently attached to glycolipids or glycoproteins in the plasma membrane. The terminal oligosaccharide sugars distinguish the three antigens. The presence or absence of the glycosyltransferases that add galactose (Gal) or *N*-acetylgalactosamine (GalNAc) to O antigen determine a person's blood type.

People whose erythrocytes lack the A antigen, the B antigen, or both on their surface normally have antibodies against the missing antigen(s) in their serum. Thus if a type A or O person receives a transfusion of type B blood, antibodies against the B antigen will bind to the introduced red cells and trigger their destruction. To prevent such harmful reactions, blood group typing and appropriate matching of blood donors and recipients are required in all transfusions (Table 10-2). ■

Lipid-Binding Motifs Help Target Peripheral Proteins to the Membrane

Many water-soluble enzymes use phospholipids as their substrates and thus must bind to membrane surfaces. Phospho-

lipases, for example, hydrolyze various bonds in the head groups of phospholipids (see Figure 10-12), and thereby play a variety of roles in cells—helping to degrade damaged or aged cell membranes, generating precursors to signaling molecules, and even serving as the active components in many snake venoms. Many such enzymes, including phospholipases, initially bind to the polar head groups of membrane phospholipids to carry out their catalytic functions. The mechanism of action of phospholipase A_2 illustrates how such water-soluble enzymes can reversibly interact with membranes and catalyze reactions at the interface of an aqueous solution and lipid surface. When this enzyme is in aqueous solution, its Ca^{2+} -containing active site is buried in a channel lined with hydrophobic amino acids. The enzyme binds with greatest affinity to bilayers composed of negatively charged phospholipids (e.g., phosphatidylserine). This finding suggests that the rim of positively charged lysine and arginine residues around the entrance to the catalytic channel is particularly important in binding (Figure 10-21a). Binding induces a conformational change in phospholipase A_2 that strengthens its binding to the phospholipid heads and opens the hydrophobic channel. As a phospholipid molecule moves from the bilayer into the channel, the enzyme-bound Ca^{2+} binds to the phosphate in the head group, thereby positioning the ester bond to be cleaved in the catalytic site (Figure 10-21b) and so releasing the acyl chain.

Proteins Can Be Removed from Membranes by Detergents or High-Salt Solutions

Membrane proteins are often difficult to purify and study, mostly because of their tight association with membrane lipids and other membrane proteins. *Detergents* are amphipathic molecules that disrupt membranes by intercalating into phospholipid bilayers and can thus be used to solubilize lipids and many membrane proteins. The hydrophobic part of a detergent molecule is attracted to the phospholipid hydrocarbons and mingles with them readily; the hydrophilic part is strongly attracted to water. Some detergents such as the bile salts are natural products, but most are synthetic molecules developed for cleaning and for dispersing mixtures of oil and water in the food industry (e.g., creamy peanut butter)

TABLE 10-2 ABO Blood Groups

Blood Group	Antigens on RBCs*	Serum Antibodies	Can Receive Blood Types
A	A	Anti-B	A and O
B	B	Anti-A	B and O
AB	A and B	None	All
O	O	Anti-A and anti-B	O

*See Figure 10-20 for antigen structures.

FIGURE 10-21 Lipid-binding surface and mechanism of action of phospholipase A₂. (a) A structural model of the enzyme showing the surface that interacts with a membrane. This lipid-binding surface contains a rim of positively charged arginine and lysine residues, shown in blue surrounding the cavity of the catalytic active site, in which a substrate lipid (red stick structure) is bound. (b) Diagram of catalysis by phospholipase A₂. When docked on a model lipid membrane, positively charged residues of the binding site bind to negatively charged polar groups at the membrane surface. This binding triggers a small conformational change, opening a channel lined with hydrophobic amino acids that leads from the bilayer to the catalytic site. As a phospholipid moves into the channel, an enzyme-bound Ca²⁺ ion (green) binds to the head group, positioning the ester bond to be cleaved (red) next to the catalytic site. [Part (a) adapted from M. H. Gelb et al., 1999, *Curr. Opin. Struct. Biol.* **9**:428. Part (b), see D. Blow, 1991, *Nature* **351**:444.]

(Figure 10-22). Ionic detergents, such as sodium deoxycholate and sodium dodecylsulfate (SDS), contain a charged group; nonionic detergents, such as Triton X-100 and octylglucoside, lack a charged group. At very low concentrations, detergents dissolve in pure water as isolated molecules. As the concentration increases, the molecules begin to form micelles—small, spherical aggregates in which the hydrophilic parts of the molecules face outward and the hydrophobic parts cluster in the center (see Figure 10-3c). The *critical micelle concentration* (CMC) at which micelles form is characteristic of each detergent and is a function of the structures of its hydrophobic and hydrophilic parts.

Ionic and nonionic detergents interact differently with proteins and have different uses in the lab. Ionic detergents bind to the exposed hydrophobic regions of membrane proteins as well as to the hydrophobic cores of water-soluble proteins. Because of their charge, these detergents can also disrupt ionic and hydrogen bonds. At high concentrations, for example, sodium dodecylsulfate completely denatures proteins by binding to every side chain, a property that is exploited in SDS gel electrophoresis (see Figure 3-36). Nonionic detergents generally do not denature proteins and are thus useful in extracting proteins in their folded and active form from membranes before the proteins are purified. Protein-protein interactions, especially the weaker ones, can be sensitive to both ionic and nonionic detergents.

At high concentrations (above the CMC), nonionic detergents solubilize biological membranes by forming mixed micelles of detergent, phospholipid, and integral membrane proteins, bulky hydrophobic structures that do not dissolve in aqueous solution (Figure 10-23, top). At low concentrations (below the CMC), these detergents bind to the hydrophobic regions of most integral membrane proteins, but without forming micelles, allowing them to remain soluble in aqueous solution (Figure 10-23, bottom). Creating such an aqueous solution of integral membrane proteins is a necessary first step in protein purification.

FIGURE 10-22 Structures of four common detergents. The hydrophobic part of each molecule is shown in yellow; the hydrophilic part, in blue. The bile salt sodium deoxycholate is a natural product; the others are synthetic. Although ionic detergents commonly cause denaturation of proteins, nonionic detergents do not and are thus useful in solubilizing integral membrane proteins.

FIGURE 10-23 Solubilization of integral membrane proteins by nonionic detergents.

At a concentration higher than its critical micelle concentration (CMC), a detergent solubilizes lipids and integral membrane proteins, forming mixed micelles containing detergent, protein, and lipid molecules. At concentrations below the CMC, nonionic detergents (e.g., octylglucoside, Triton X-100) can dissolve membrane proteins without forming micelles by coating the membrane-spanning regions.

Treatment of cultured cells with a buffered salt solution containing a nonionic detergent such as Triton X-100 extracts water-soluble proteins as well as integral membrane proteins. As noted earlier, the exoplasmic and cytosolic domains of integral membrane proteins are generally hydrophilic and soluble in water. The membrane-spanning domains, however, are rich in hydrophobic and uncharged residues (see Figure 10-14). When separated from membranes, these exposed hydrophobic segments tend to interact with one another, causing the protein molecules to aggregate and precipitate from aqueous solutions. The hydrophobic parts of nonionic detergent molecules preferentially bind to the hydrophobic segments of transmembrane proteins, preventing protein aggregation and allowing the proteins to remain in the aqueous solution. Detergent-solubilized transmembrane proteins can then be purified by affinity chromatography and other techniques used in purifying water-soluble proteins (see Chapter 3).

As discussed previously, most peripheral membrane proteins are bound to specific transmembrane proteins or membrane phospholipids by ionic or other weak noncovalent interactions. Generally, peripheral proteins can be removed from the membrane by solutions of high ionic strength (high salt concentrations), which disrupt ionic bonds, or by chemicals that bind divalent cations such as Mg^{2+} . Unlike integral proteins, most peripheral proteins are soluble in aqueous solution and need not be solubilized by nonionic detergents.

surrounding the cytosolic and exoplasmic faces of the membrane (see Figures 10-14, 10-15, and 10-17).

- Fatty acyl side chains as well as the polar head groups of membrane lipids pack tightly and irregularly around the hydrophobic segments of integral membrane proteins (see Figure 10-16).
- The porins, unlike other integral proteins, contain membrane-spanning β sheets that form a barrel-like channel through the bilayer (see Figure 10-18).
- Long-chain lipids attached to certain amino acids anchor some proteins to one or the other membrane leaflet (see Figure 10-19).
- All transmembrane proteins and glycolipids are asymmetrically oriented in the bilayer. Invariably, carbohydrate chains are present only on the exoplasmic surface of a glycoprotein or glycolipid.
- Many water-soluble enzymes (e.g., phospholipases) use phospholipids as their substrates and must bind to the membrane surface to carry out their function. Such binding is often due to the attraction between positive charges on basic residues in the protein and negative charges on phospholipid head groups in the bilayer.
- Transmembrane proteins are selectively extracted (solubilized) and purified with the use of nonionic detergents.

KEY CONCEPTS of Section 10.2

Membrane Proteins: Structure and Basic Functions

- Biological membranes usually contain both integral (transmembrane) proteins and peripheral membrane proteins, which do not enter the hydrophobic core of the bilayer (see Figure 10-1).
- Most integral membrane proteins contain one or more membrane-spanning hydrophobic α helices bracketed by hydrophilic domains that extend into the aqueous environment

10.3 Phospholipids, Sphingolipids, and Cholesterol: Synthesis and Intracellular Movement

In this section, we consider some of the special challenges that a cell faces in synthesizing and transporting lipids, which are poorly soluble in the aqueous interior of cells. The focus of our discussion will be the biosynthesis and movement of the major lipids found in cellular membranes—phospholipids, sphingolipids, and cholesterol—and their precursors. In lipid biosynthesis, water-soluble precursors are assembled into

membrane-associated intermediates that are then converted into membrane lipid products. The movement of lipids, especially membrane components, between different organelles is critical for maintaining the proper composition and properties of membranes and overall cell structure.

A fundamental principle of membrane biosynthesis is that cells synthesize new membranes only by the expansion of existing membranes. (The one exception may be autophagy, where new membrane is formed first through the formation of an autophagic crescent, the construction of which involves modification of phosphatidylethanolamine with the ubiquitin-like modifier Atg8 [see Figure 14-35].) Although some early steps in the synthesis of membrane lipids take place in the cytoplasm, the final steps are catalyzed by enzymes bound to pre-existing cellular membranes, and the products are incorporated into the membranes as they are generated. Evidence for this phenomenon is seen when cells are briefly exposed to radioactive precursors (e.g., phosphate or fatty acids): all the phospholipids and sphingolipids incorporating these precursor substances are associated with intracellular membranes; as expected from the hydrophobicity of the fatty acyl chains, none are found free in the cytosol. After they are formed, membrane lipids must be distributed appropriately both in leaflets of a given membrane and among the independent membranes of different organelles in eukaryotic cells, as well as in the plasma membrane. Here, we consider how this precise lipid distribution is accomplished; in Chapters 13 and 14 we discuss how membrane proteins are inserted into cell membranes and trafficked to their appropriate location within the cell.

Fatty Acids Are Assembled from Two-Carbon Building Blocks by Several Important Enzymes

Fatty acids (Chapter 2) play a number of important roles in cells. In addition to being a cellular fuel source (see discussion of aerobic oxidation in Chapter 12), fatty acids are key components of both the phospholipids and sphingolipids making up cell membranes; they also anchor some proteins to cellular membranes (see Figure 10-19). Thus the regulation of fatty acid synthesis plays a key role in the regulation of membrane synthesis as a whole. The major fatty acids in phospholipids contain 14, 16, 18, or 20 carbon atoms and include both saturated and unsaturated chains. The fatty acyl chains found on sphingolipids can be longer than those in the phosphoglycerides, containing up to 26 carbon atoms, and may bear other chemical modifications (e.g., hydroxylation) as well.

Fatty acids are synthesized from the two-carbon building block acetate, CH_3COO^- . In cells, both acetate and the intermediates in fatty acid biosynthesis are esterified to the large water-soluble molecule coenzyme A (CoA), as exemplified by the structure of acetyl CoA:

Acetyl CoA is an important intermediate in the metabolism of glucose, fatty acids, and many amino acids, as detailed in Chapter 12. It also contributes acetyl groups in many biosynthetic pathways. **Saturated** fatty acids (no carbon-carbon double bonds) containing 14 or 16 carbon atoms are made from acetyl CoA by two enzymes, *acetyl-CoA carboxylase* and *fatty acid synthase*. In animal cells, these enzymes are found in the cytosol; in plants, they are found in chloroplasts. Palmitoyl CoA (16-carbon fatty acyl group linked to CoA) can be elongated to 18–24 carbons by the sequential addition of two-carbon units in the endoplasmic reticulum (ER) or sometimes in the mitochondrion. Desaturase enzymes, also located in the ER, introduce double bonds at specific positions in some fatty acids, yielding **unsaturated** fatty acids. Oleoyl CoA (oleate linked to CoA, see Table 2-4), for example, is formed by removal of two H atoms from stearoyl CoA. In contrast to free fatty acids, fatty acyl CoA derivatives are soluble in aqueous solutions because of the hydrophilicity of the CoA segment.

Small Cytosolic Proteins Facilitate Movement of Fatty Acids

In order to be transported through the cell cytoplasm, free, or unesterified, fatty acids (those unlinked to a CoA), commonly are bound by *fatty-acid-binding proteins* (FABPs), which belong to a group of small cytosolic proteins that facilitate the intracellular movement of many lipids. These proteins contain a hydrophobic pocket lined by β sheets (Figure 10-24). A long-chain fatty acid can fit into this pocket and interact non-covalently with the surrounding protein.

The expression of cellular FABPs is regulated coordinately with cellular requirements for the uptake and release of fatty acids. Thus FABP levels are high in active muscles that are using fatty acids for generation of ATP, and in adipocytes (fat-storing cells) when they are either taking up fatty acids to be stored as triglycerides or releasing fatty acids for use by other cells. The importance of FABPs in fatty acid metabolism is highlighted by the observations that they can compose as much as 5 percent of all cytosolic proteins in the liver and that genetic inactivation of cardiac muscle FABP converts the heart from a muscle that primarily burns fatty acids for energy into one that primarily burns glucose.

Fatty Acids Are Incorporated into Phospholipids Primarily on the ER Membrane

Fatty acids are not directly incorporated into phospholipids; rather, in eukaryotic cells they are first converted into CoA esters. The subsequent synthesis of phospholipids such as the phosphoglycerides is carried out by enzymes associated with

FIGURE 10-24 Binding of a fatty acid to the hydrophobic pocket of a fatty-acid-binding protein (FABP). The crystal structure of adipocyte FABP (ribbon diagram) reveals that the hydrophobic binding pocket is generated from two β sheets that are nearly at right angles to each other, forming a clam-shell-like structure. A fatty acid (carbons yellow; oxygens red) interacts noncovalently with hydrophobic amino acid residues within this pocket. [See A. Reese-Wagoner et al., 1999, *Biochim. Biophys. Acta* 23:1441(2-3):106-116.]

the cytosolic face of the ER membrane, usually the smooth ER, in animal cells; through a series of steps, fatty acyl CoAs, glycerol 3-phosphate, and polar head-group precursors are linked together and then inserted into the ER membrane (Figure 10-25). The fact that these enzymes are located on the cytosolic side of the membrane means that there is an inherent asymmetry in membrane biogenesis: new membranes are initially synthesized only on one leaflet—a fact with important consequences for the asymmetric distribution of lipids in membrane leaflets. Once synthesized on the ER, phospholipids are transported to other organelles and to the plasma membrane. Mitochondria synthesize some of their own membrane lipids and import others.

Sphingolipids are also synthesized indirectly from multiple precursors. Sphingosine, the building block of these lipids, is made in the ER, beginning with the coupling of a palmitoyl group from palmitoyl CoA to serine; the subsequent addition of a second fatty acyl group to form *N*-acyl sphingosine

(ceramide) also takes place in the ER. Later, in the Golgi, a polar head group is added to ceramide yielding *sphingomyelin*, whose head group is phosphorylcholine, and various *glycosphingolipids*, in which the head group may be a monosaccharide or a more complex oligosaccharide (see Figure 10-8b). Some sphingolipid synthesis can also take place in mitochondria. In addition to serving as the backbone for sphingolipids, ceramide and its metabolic products are important signaling molecules that can influence cell growth, proliferation, endocytosis, resistance to stress, and programmed cell death (apoptosis).

FIGURE 10-25 Phospholipid synthesis in ER membrane. Because phospholipids are amphipathic molecules, the last stages of their multistep synthesis take place at the interface between a membrane and the cytosol and are catalyzed by membrane-associated enzymes. **Step 1:** Two fatty acids from fatty acyl CoA are esterified to the phosphorylated glycerol backbone, forming phosphatidic acid, whose two long hydrocar-

bon chains anchor the molecule to the membrane. **Step 2:** A phosphatase converts phosphatidic acid into diacylglycerol. **Step 3:** A polar head group (e.g., phosphorylcholine) is transferred from cytosine diphosphate (CDP-choline) to the exposed hydroxyl group. **Step 4:** Flippase proteins catalyze the movement of phospholipids from the cytosolic leaflet in which they are initially formed to the exoplasmic leaflet.

After their synthesis is completed in the Golgi, sphingolipids are transported to other cellular compartments through vesicle-mediated mechanisms similar to those for the transport of proteins, discussed in Chapter 14. Any type of vesicular transport results in movement not only of the protein payload, but also of the lipids that compose the vesicular membrane. In addition, phospholipids such as phosphoglycerides, as well as cholesterol, can move between organelles by different mechanisms, described below.

Flippases Move Phospholipids from One Membrane Leaflet to the Opposite Leaflet

Even though phospholipids are initially incorporated into the cytosolic leaflet of the ER membrane, various phospholipids are asymmetrically distributed in the two leaflets of the ER membrane and of other cellular membranes. As noted above, phospholipids do not readily flip-flop from one leaflet to the other. For the ER membrane to expand by growth of both leaflets and have asymmetrically distributed phospholipids, its phospholipid components must be able to move from one membrane leaflet to the other. Although the mechanisms employed to generate and maintain membrane

phospholipid asymmetry are not well understood, it is clear that flippases play a key role. As described in Chapter 11, these integral membrane proteins use the energy of ATP hydrolysis to facilitate the movement of phospholipid molecules from one leaflet to the other (see Figure 11-15).

Cholesterol Is Synthesized by Enzymes in the Cytosol and ER Membrane

Next we focus on cholesterol, the principal sterol in animal cells. Cholesterol is synthesized mainly in the liver. The first steps of cholesterol synthesis (Figure 10-26)—conversion of three acetyl groups linked to CoA (acetyl CoA) forming the 6-carbon molecule β -hydroxy- β -methylglutaryl linked to CoA (HMG-CoA)—take place in the cytosol. The conversion of HMG-CoA into mevalonate, the key rate-controlling step in cholesterol biosynthesis, is catalyzed by *HMG-CoA reductase*, an ER integral membrane protein, even though both its substrate and its product are water soluble. The water-soluble catalytic domain of HMG-CoA reductase extends into the cytosol, but its eight transmembrane α helices firmly embed the enzyme in the ER membrane. Five of the transmembrane α helices compose the so-called *sterol-sensing domain* and regulate

FIGURE 10-26 Cholesterol biosynthetic pathway. The regulated rate-controlling step in cholesterol biosynthesis is the conversion of β -hydroxy- β -methylglutaryl CoA (HMG-CoA) into mevalonic acid by HMG-CoA reductase, an ER-membrane protein. Mevalonate is then converted into isopentenyl pyrophosphate (IPP), which has the basic

five-carbon isoprenoid structure. IPP can be converted into cholesterol and into many other lipids, often through the polyisoprenoid intermediates shown here. Some of the numerous compounds derived from isoprenoid intermediates and cholesterol itself are indicated.

enzyme stability. When levels of cholesterol in the ER membrane are high, binding of cholesterol to this domain causes the protein to bind to two other integral ER membrane proteins, Insig-1 and Insig-2. This in turn induces ubiquitination (see Figure 3-29) of HMG-CoA reductase and its degradation by the proteasome pathway, reducing the production of mevalonate, the key intermediate in cholesterol biosynthesis.

Atherosclerosis, frequently called cholesterol-dependent clogging of the arteries, is characterized by the progressive deposition of cholesterol and other lipids, cells, and extracellular matrix material in the inner layer of the wall of an artery. The resulting distortion of the artery's wall can lead, either alone or in combination with a blood clot, to major blockage of blood flow. Atherosclerosis accounts for 75 percent of deaths due to cardiovascular disease in the United States.

Perhaps the most successful anti-atherosclerosis medications are the *statins*. These drugs bind to HMG-CoA reductase and directly inhibit its activity, thereby lowering cholesterol biosynthesis. As a consequence, the amount of low-density lipoproteins (see Figure 14-27)—the small, membrane-enveloped particles containing cholesterol esterified to fatty acids that often and rightly are called “bad cholesterol”—drops in the blood, reducing the formation of atherosclerotic plaques. ■

Mevalonate, the six-carbon product formed by HMG-CoA reductase, is converted in several steps into the five-carbon isoprenoid compound isopentenyl pyrophosphate (IPP) and its stereoisomer, dimethylallyl pyrophosphate (DMPP) (see Figure 10-26). These reactions are catalyzed by cytosolic enzymes, as are the subsequent reactions in the cholesterol synthesis pathway, in which six IPP units condense to yield squalene, a branched-chain 30-carbon intermediate. Enzymes bound to the ER membrane catalyze the multiple reactions that convert squalene into cholesterol in mammals or into related sterols in other species. One of the intermediates in

this pathway, farnesyl pyrophosphate, is the precursor of the prenyl lipid that anchors Ras and related proteins to the cytosolic surface of the plasma membrane (see Figure 10-19) as well as other important biomolecules (see Figure 10-26).

Cholesterol and Phospholipids Are Transported Between Organelles by Several Mechanisms

As already noted, the final steps in the synthesis of cholesterol and phospholipids take place primarily in the ER. Thus the plasma membrane and the membranes bounding other organelles must obtain these lipids by means of one or more intracellular transport processes. Membrane lipids can and do accompany both soluble and membrane proteins during the secretory pathway described in Chapter 14; membrane vesicles bud from the ER and fuse with membranes in the Golgi complex, and other membrane vesicles bud from the Golgi complex and fuse with the plasma membrane (Figure 10-27a). However, several lines of evidence suggest that there is substantial inter-organelle movement of cholesterol and phospholipids through other mechanisms. For example, chemical inhibitors of the classic secretory pathway and mutations that impede vesicular traffic in this pathway do not prevent cholesterol or phospholipid transport between membranes.

A second mechanism entails direct protein-mediated contact of ER or ER-derived membranes with membranes of other organelles (Figure 10-27b). In the third mechanism, small lipid-transfer proteins facilitate the exchange of phospholipids or cholesterol between different membranes (Figure 10-27c). Although such transfer proteins have been identified in assays *in vitro*, their role in intracellular movements of most phospholipids is not well defined. For instance, mice with a knockout mutation in the gene encoding the phosphatidylcholine-transfer protein appear to be normal in most respects, indicating that this protein is not essential for cellular phospholipid metabolism.

As noted earlier, the lipid compositions of different organelle membranes vary considerably (see Table 10-1). Some

FIGURE 10-27 Proposed mechanisms of transport of cholesterol and phospholipids between membranes. In mechanism (a), vesicles transfer lipids between membranes. In mechanism (b), lipid transfer is a consequence of direct contact between membranes that is mediated

by membrane-embedded proteins. In mechanism (c), transfer is mediated by small, soluble lipid-transfer proteins. [Adapted from F. R. Maxfield and D. Wustner, 2002, *J. Clin. Invest.* 110:891.]

of these differences are due to different sites of synthesis. For example, a phospholipid called cardiolipin, which is localized to the mitochondrial membrane, is made only in mitochondria and little is transferred to other organelles. Differential transport of lipids also plays a role in determining the lipid compositions of different cellular membranes. For instance, even though cholesterol is made in the ER, the cholesterol concentration (cholesterol-to-phospholipid molar ratio) is ~1.5–13-fold higher in the plasma membrane than in other organelles (ER, Golgi, mitochondrion, lysosome). Although the mechanisms responsible for establishing and maintaining these differences are not well understood, we have seen that the distinctive lipid composition of each membrane has a major influence on its physical and biological properties.

KEY CONCEPTS of Section 10.3

Phospholipids, Sphingolipids, and Cholesterol: Synthesis and Intracellular Movement

- Saturated and unsaturated fatty acids of various chain lengths are components of phospholipids and sphingolipids.
- Fatty acids are synthesized from acetyl CoA by water-soluble enzymes and modified by elongation and desaturation in the endoplasmic reticulum (ER).
- Free fatty acids are transported within cells by fatty-acid-binding proteins (FABPs).
- Fatty acids are incorporated into phospholipids through a multi-step process. The final steps in the synthesis of phosphoglycerides and sphingolipids are catalyzed by membrane-associated enzymes primarily on the cytosolic face of the ER (see Figure 10-25).
- Each type of newly synthesized lipid is incorporated into the preexisting membranes on which it is made; thus, membranes are themselves the platform for the synthesis of new membrane material.
- Most membrane phospholipids are preferentially distributed in either the exoplasmic or the cytosolic leaflet. This asymmetry results in part from the action of phospholipid flippases, which flip lipids from one leaflet to the other.
- The initial steps in cholesterol biosynthesis take place in the cytosol, whereas the last steps are catalyzed by enzymes associated with the ER membrane.
- The rate-controlling step in cholesterol biosynthesis is catalyzed by HMG-CoA reductase, whose transmembrane segments are embedded in the ER membrane and contain a sterol-sensing domain.
- Considerable evidence indicates that Golgi-independent vesicular transport, direct protein-mediated contacts between different membranes, soluble protein carriers, or all three may account for some inter-organelle transport of cholesterol and phospholipids (see Figure 10-27).

Perspectives for the Future

One fundamental question in lipid biology concerns the generation, maintenance, and function of the asymmetric distribution of lipids within the leaflets of one membrane and the variation in lipid composition among the membranes of different organelles. What are the mechanisms underlying this complexity, and why is such complexity needed? We already know that certain lipids can specifically interact with and influence the activity of some proteins. For example, the large multimeric proteins that participate in oxidative phosphorylation in the inner mitochondrial membrane appear to assemble into supercomplexes whose stability may depend on the physical properties and binding of specialized phospholipids such as cardiolipin (see Chapter 12).

The existence of lipid rafts in biological membranes and their function in cell signaling remains a topic of heated debate. Many biochemical studies using model membranes show that stable lateral assemblies of sphingolipids and cholesterol—lipid rafts—can facilitate selective protein-protein interactions by excluding or including specific proteins. But whether or not lipid rafts exist in natural biological membranes, as well as their dimensions and dynamics, is under intense investigation. New biophysical and microscopic tools are beginning to provide a more solid basis for their existence, size, and behavior.

Despite considerable progress in our understanding of the cellular metabolism and movement of lipids, the mechanisms for transporting cholesterol and phospholipids between organelle membranes remain poorly characterized. In particular, we lack a detailed understanding of how various transport proteins move lipids from one membrane leaflet to another (flippase activity) and into and out of cells. Such understanding will require a determination of high-resolution structures of these molecules, their capture in various stages of the transport process, and careful kinetic and other biophysical analyses of their function, similar to the approaches discussed in Chapter 11 for elucidating the operation of ion channels and ATP-powered pumps.

Recent advances in solubilizing and crystallizing integral membrane proteins have led to the delineation of the molecular structures of many important types of proteins, such as ion channels, G protein-coupled receptors, ATP-powered ion pumps, and aquaporins, as we will see in Chapter 11. However, many important classes of membrane proteins have proven recalcitrant to even these new approaches. For example, we lack the structure of any protein that transports glucose into a eukaryotic cell. As we will learn in Chapters 15 and 16, many classes of receptors span the plasma membrane with one or more α helices. Perhaps surprisingly, we lack the molecular structure of the transmembrane segment of any single-pass eukaryotic cell-surface receptor, and so many aspects of the function of these proteins are still mysterious. The transmittal of information across the membrane, as it occurs when a single-pass receptor binds an appropriate ligand, remains to be described at adequate molecular resolution. Elucidating the molecular structures of

these and many other types of membrane proteins will clarify many aspects of molecular cell biology.

Key Terms

amphipathic 445	lipid raft 454
aquaporin 458	liposome 445
atherosclerosis 468	lumen 448
cholesterol 450	membrane transport protein 443
cilium 448	micelle 445
cytoskeleton 443	peripheral membrane protein 456
cytosolic face 447	phosphoglyceride 448
exoplasmic face 447	phospholipase 454
flagellum 448	phospholipid bilayer 445
flippase 454	plasma membrane 443
glycolipid 450	porin 458
glycoprotein 461	receptor protein 443
hydrophilic 445	saturated 465
hydrophobic 445	sphingolipid 450
integral membrane protein 456	statin 468
lectin 461	sterol 450
lipid-anchored membrane protein 456	unsaturated 465
lipid droplet 455	

Review the Concepts

- When viewed by electron microscopy, the lipid bilayer is often described as looking like a railroad track. Explain how the structure of the bilayer creates this image.
- Explain the following statement: The structure of all biomembranes depends on the chemical properties of phospholipids, whereas the function of each specific biomembrane depends on the specific proteins associated with that membrane.
- Biomembranes contain many different types of lipid molecules. What are the three main types of lipid molecules found in biomembranes? How are the three types similar, and how are they different?
- Lipid bilayers are considered to be two-dimensional fluids. What does this mean? What drives the movement of lipid molecules and proteins within the bilayer? How can such movement be measured? What factors affect the degree of membrane fluidity?
- Why are water-soluble substances unable to freely cross the lipid bilayer of the cell membrane? How does the cell overcome this permeability barrier?
- Name the three groups into which membrane-associated proteins may be classified. Explain the mechanism by which each group associates with a biomembrane.

7. Identify the following membrane-associated proteins based on their structure: (a) tetramers of identical subunits, each with six membrane-spanning α helices; (b) trimers of identical subunits, each with 16 β sheets forming a barrel-like structure.

8. Proteins may be bound to the exoplasmic or cytosolic face of the plasma membrane by way of covalently attached lipids. What are the three types of lipid anchors responsible for tethering proteins to the plasma membrane bilayer, and which type is used by cell-surface proteins that face the external medium and by glycosylated proteoglycans?

9. Although both faces of a biomembrane are composed of the same general types of macromolecules, principally lipids and proteins, the two faces of the bilayer are not identical. What accounts for the asymmetry between the two faces?

10. What are detergents? How do ionic and nonionic detergents differ in their ability to disrupt cell membrane structure?

11. What is the likely identity of these membrane-associated proteins: (a) released from the membrane with a high-salt solution causing disruption of ionic linkages; (b) not released from the membrane upon exposure to a high-salt solution alone, but released when incubated with an enzyme that cleaves phosphate-glycerol bonds and covalent linkages are disrupted; (c) not released from the membrane upon exposure to a high-salt solution, but released after addition of the detergent sodium dodecyl sulfate (SDS). Will the activity of the protein released in part (c) be preserved following release?

12. Following the production of membrane extracts using the nonionic detergent Triton X-100, you analyze the membrane lysates via mass spectrometry and note a high content of cholesterol and sphingolipids. Furthermore, biochemical analysis of the lysates reveals potential kinase activity. What have you likely isolated?

13. Phospholipid biosynthesis at the interface between the endoplasmic reticulum (ER) and the cytosol presents a number of challenges that must be solved by the cell. Explain how each of the following is handled.

a. The substrates for phospholipid biosynthesis are all water soluble, yet the end products are not.

b. The immediate site of incorporation of all newly synthesized phospholipids is the cytosolic leaflet of the ER membrane, yet phospholipids must be incorporated into both leaflets.

c. Many membrane systems in the cell, for example the plasma membrane, are unable to synthesize their own phospholipids, yet these membranes must also expand if the cell is to grow and divide.

14. What are the common fatty acid chains in phosphoglycerides, and why do these fatty acid chains differ in their number of carbon atoms by multiples of 2?

15. Fatty acids must associate with lipid chaperones in order to move within the cell. Why are these chaperones needed, and what is the name given to a group of proteins that are responsible for this intracellular trafficking of fatty acids? What is the key distinguishing feature of these proteins that allows fatty acids to move within the cell?

16. The biosynthesis of cholesterol is a highly regulated process. What is the key regulated enzyme in cholesterol biosynthesis? This enzyme is subject to feedback inhibition. What is feedback inhibition? How does this enzyme sense cholesterol levels in a cell?

17. Phospholipids and cholesterol must be transported from their site of synthesis to various membrane systems within cells. One way of doing this is through vesicular transport, as is the case for many proteins in the secretory pathway (Chapter 14). However, most phospholipid and cholesterol membrane-to-membrane transport in cells is not by vesicular transport. What is the evidence for this statement? What appear to be the major mechanisms for phospholipid and cholesterol transport?

18. Explain the mechanism by which statins lower “bad” cholesterol.

Analyze the Data

1. The behavior of receptor X (XR), a transmembrane protein present in the plasma membrane of mammalian cells, is being investigated. The protein has been engineered as a fusion protein containing the green fluorescent protein (GFP) at its N-terminus. GFP-XR is a functional protein and can replace XR in cells.

a. Cells expressing GFP-XR or artificial lipid vesicles (liposomes) containing GFP-XR are subjected to fluorescence recovery after photobleaching (FRAP). The intensity of the fluorescence of a small spot on the surface of the cells (solid line) or on the surface of the liposomes (dashed line) is measured prior to and following laser bleaching (arrow). The data are shown below.

What explanation could account for the differing behavior of GFP-XR in liposomes versus in the plasma membrane of a cell?

b. Tiny gold particles can be attached to individual molecules and their movement then followed in a light microscope by single-particle tracking. This method allows one to observe the behavior of individual proteins in a membrane.

The tracks generated during a 5-second observational period by a gold particle attached to XR present in a cell (left) or in a liposome (middle) or to XR adhered to a microscope slide (right) are shown below.

What additional information do these data provide beyond what can be determined from the FRAP data?

c. Fluorescence resonance energy transfer (FRET) is a technique by which a fluorescent molecule, following its excitation with the appropriate wavelength of light, can transfer its emission energy to and excite a nearby different fluorescent molecule (see Figure 15-18). Cyan fluorescent protein (CFP) and yellow fluorescent protein (YFP) are related to GFP but fluoresce at cyan and yellow wavelengths rather than at green. If CFP is excited with the appropriate wavelength of light and a YFP molecule is very near, then energy can be transferred from CFP emission and used to excite YFP, as indicated by a loss of emission of cyan fluorescence and an increase in emission of yellow fluorescence. CFP-XR and YFP-XR are expressed together in a cell line or are both incorporated into liposomes. The number of molecules of YFP-XR and CFP-XR per cm^2 of membrane is equivalent in the cells and the liposomes. The cells and liposomes are then irradiated with a wavelength of light that causes CFP but not YFP to fluoresce. The amount of cyan (CFP) and yellow (YFP) fluorescence emitted by the cells (solid line) or liposomes (dashed line) is then monitored, as shown below.

What can be deduced about XR from these data?

2. After performing differential scanning calorimetry (a procedure used to determine the transition temperature of a given membrane by recording the amount of heat absorbed prior to

phase transition [solid to fluid state]) on membranes from three different organisms, you obtain the following results:

Which of the following statements is likely true about the lipid composition of membrane C?

- i. It has high levels of saturated hydrocarbons and long hydrocarbon tails compared to A and B.
- ii. It has high levels of saturated hydrocarbons and short hydrocarbon tails compared to A and B.
- iii. It has high levels of unsaturated hydrocarbons and long hydrocarbon tails compared to A and B.
- iv. It has high levels of unsaturated hydrocarbons and short hydrocarbon tails compared to A and B.

Transmembrane Transport of Ions and Small Molecules

In all cells, the plasma membrane forms the permeability barrier that separates the cytoplasm from the exterior environment, thus defining a cell's physical and chemical boundaries. By preventing the unimpeded movement of molecules and ions into and out of cells, the plasma membrane maintains essential differences between the composition of the extracellular fluid and that of the cytosol; for example, the concentration of NaCl in the blood and extracellular fluids of animals is generally above 150 mM, similar to that of the seawater in which all cells are thought to have evolved, whereas the Na⁺ concentration in the cytosol is tenfold lower. In contrast, the potassium ion (K⁺) concentration is higher in the cytosol than outside.

Organelle membranes, which separate the cytosol from the interior of the organelle, also form permeability barriers. For example, the proton concentration in the lysosome interior, pH 5, is about 100-fold greater than that of the cytosol, and many specific metabolites accumulate at higher concen-

trations in the interior of other organelles, such as the endoplasmic reticulum or the Golgi complex, than in the cytosol.

All cellular membranes, both plasma and organelle, consist of a bilayer of phospholipids into which other lipids and specific types of proteins are embedded. It is this combination of lipids and proteins that gives cellular membranes their distinctive permeability qualities. If cellular membranes were pure phospholipid bilayers (see Figure 10-4), they would be excellent chemical barriers, impermeable to virtually all ions, amino acids, sugars, and other water-soluble molecules. In fact, only a few gases and uncharged, small, water-soluble molecules can readily diffuse across a pure phospholipid bilayer (Figure 11-1). But cellular membranes must serve not only as barriers; they must also act as conduits, selectively transporting molecules and ions from one side of the membrane to the other. Energy-rich glucose, for example, must be imported into the cell, and wastes must be shipped out.

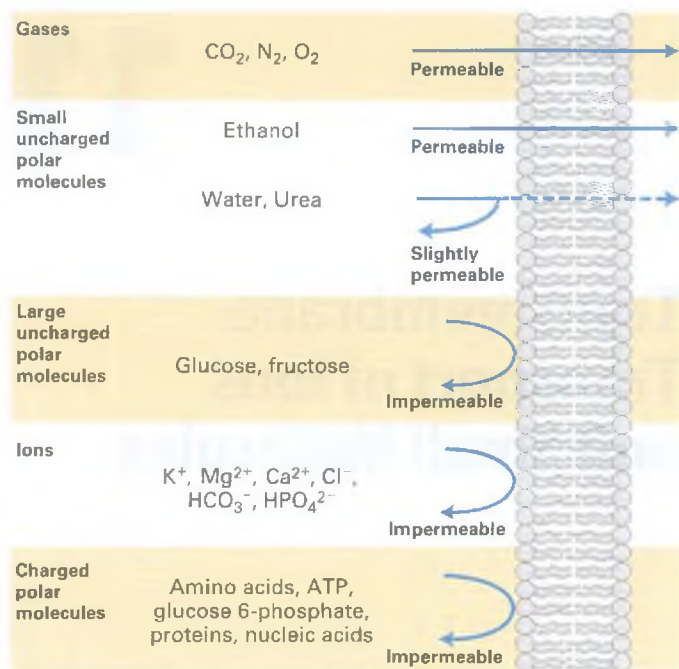

FIGURE 11-1 Relative permeability of a pure phospholipid bilayer to various molecules and ions. A bilayer is permeable to many gases and to small, uncharged, water-soluble (polar) molecules. It is slightly permeable to water, and essentially impermeable to ions and to large polar molecules.

Movement of virtually all small molecules and ions across cell membranes is mediated by **membrane transport proteins**—integral membrane proteins embedded by multiple transmembrane domains in cellular membranes. These membrane-spanning proteins act variously as shuttles, channels, or pumps for transporting molecules and ions through a membrane's hydrophobic interior. In some cases, molecules or ions are transported from a higher to a lower concentration, a thermodynamically favored process powered by an increase in entropy. Examples include the transport of water or glucose from the blood into most body cells. In other cases, molecules or ions must be pumped from a lower to a higher concentration, a thermodynamically unfavorable process that can only occur when an external source of energy is available to push the molecules “uphill” against a concentration gradient. An example is the cell's ability to concentrate protons within lysosomes to generate a low pH in the lumen. Often the required energy is provided by mechanistically coupling the energy-releasing hydrolysis of the terminal phosphoanhydride bond in ATP with the movement of a molecule or ion across the membrane. Other proteins couple the movement of one molecule or ion against its concentration gradient with the movement of another down its gradient, using the energy released by the downhill movement of one molecule or ion to thermodynamically drive the uphill movement of another. Proper functioning of any cell relies on a precise balance between such import and export of various molecules and ions.

We begin our discussion of membrane transport proteins by reviewing some of the general principles of transport across membranes and distinguishing between three major classes of such proteins. In subsequent sections, we describe the structure and operation of specific examples of each class and show how members of families of homologous transport proteins have different properties that enable different cell types to function appropriately. We also explain how both the plasma membrane and organellar membranes contain specific combinations of transport proteins that enable cells to carry out essential physiological processes, including the maintenance of cytosolic pH, the accumulation of sucrose and salts in plant cell vacuoles, and the directed flow of water in both plants and animals. The cell's resting membrane potential is an important consequence of selective ion transport across membranes, and we consider how this potential arises. Epithelial cells, such as those lining the small intestine, use a combination of membrane proteins to transport ions, sugars, and other small molecules and water from one side of the cell to the other. We will see how this understanding has led to the development of sports drinks as well as therapies for cholera.

Note that in this chapter we cover only transport of small molecules and ions; transport of larger molecules, such as proteins and oligosaccharides, is covered in Chapters 13 and 14.

11.1 Overview of Transmembrane Transport

In this section, we first describe the factors that influence the permeability of lipid membranes, and then briefly describe the three major classes of membrane transport proteins that allow molecules and ions to cross them. Different kinds of membrane-embedded proteins accomplish the task of moving molecules and ions in different ways.

Only Gases and Small Uncharged Molecules Cross Membranes by Simple Diffusion

With its dense hydrophobic core, a phospholipid bilayer is largely impermeable to water-soluble molecules and ions. Only gases, such as O₂ and CO₂, and small uncharged polar molecules, such as urea and ethanol, can readily move by **simple diffusion** across an artificial membrane composed of pure phospholipid or of phospholipid and cholesterol (see Figure 11-1). Such molecules also can diffuse across cellular membranes without the aid of transport proteins. No metabolic energy is expended because movement is from a high to a low concentration of the molecule, down its chemical concentration gradient. As noted in Chapter 2, such movements are spontaneous because they have a positive ΔS value (increase in entropy) and thus a negative ΔG (decrease in free energy).

The relative diffusion rate of any substance across a pure phospholipid bilayer is proportional to its concentration gradient across the bilayer and to its hydrophobicity and size;

the movement of charged molecules is also affected by any electric potential across the membrane. When a pure phospholipid bilayer separates two aqueous spaces, or “compartments,” membrane permeability can be easily determined by adding a small amount of radioactive material to one compartment and measuring its rate of appearance in the other compartment. The greater the concentration gradient of the substance, the faster its rate of movement across a bilayer.

The hydrophobicity of a substance is determined by measuring its partition coefficient K , the equilibrium constant for its partition between oil and water. The higher a substance's partition coefficient (the greater the fraction found in oil relative to water), the more lipid soluble it is and, therefore, the faster its rate of movement across a bilayer. The first and rate-limiting step in transport by simple diffusion is movement of a molecule from the aqueous solution into the hydrophobic interior of the phospholipid bilayer, which resembles olive oil in its chemical properties. This is the reason that the more hydrophobic a molecule is, the faster it diffuses across a pure phospholipid bilayer. For example, diethylurea, with an ethyl group attached to each nitrogen atom:

has a K of 0.01, whereas urea

has a K of 0.0002. Diethylurea, which is 50 times ($0.01/0.0002$) more hydrophobic than urea, will therefore diffuse through phospholipid bilayer membranes about 50 times faster than urea. Similarly, fatty acids with longer hydrocarbon chains are more hydrophobic than those with shorter chains and at all concentrations will diffuse more rapidly across a pure phospholipid bilayer.

If a substance carries a net charge, its movement across a membrane is influenced by both its concentration gradient and the **membrane potential**, the electric potential (voltage) across the membrane. The combination of these two forces, called the **electrochemical gradient**, determines the energetically favorable direction of movement of a charged molecule across a membrane. The electric potential that exists across most cellular membranes results from a small imbalance in the concentration of positively and negatively charged ions on the two sides of the membrane. We discuss how this ionic imbalance, and resulting potential, arise and are maintained in Sections 11.4 and 11.5.

Three Main Classes of Membrane Proteins Transport Molecules and Ions Across Biomembranes

As is evident from Figure 11-1, very few molecules and no ions can cross a pure phospholipid bilayer at appreciable rates by simple diffusion. Thus transport of most molecules into and out of cells requires the assistance of specialized membrane proteins. Even in the case of molecules with relatively large partition coefficients (e.g., urea, fatty acids), and certain gases such as CO_2 (carbon dioxide) and NH_3 (ammonia), transport is frequently accelerated by specific proteins because simple diffusion usually does not occur rapidly enough to meet cellular needs.

All transport proteins are transmembrane proteins containing multiple membrane-spanning segments that generally are α helices. By forming a protein-lined pathway across the membrane, transport proteins are thought to allow movement of hydrophilic substances without their coming into contact with the hydrophobic interior of the membrane. Here we introduce the three main types of membrane transport proteins covered in this chapter (Figure 11-2).

FIGURE 11-2 Overview of membrane transport proteins. Gradients are indicated by triangles with the tip pointing toward lower concentration, electric potential, or both. **1** Pumps utilize the energy released by ATP hydrolysis to power movement of specific ions or small molecules (red circles) against their electrochemical gradient. **2** Channels permit movement of specific ions (or water) down their electrochemical gradient. **3** Transporters, which fall into three groups, facilitate movement of specific small molecules or ions. Uniporters

transport a single type of molecule down its concentration gradient **3A**. Cotransport proteins (symporters, **3B**, and antiporters, **3C**) catalyze the movement of one molecule *against* its concentration gradient (black circles), driven by movement of one or more ions down an electrochemical gradient (red circles). Differences in the mechanisms of transport by these three major classes of proteins account for their varying rates of solute movement.

ATP-powered pumps (or simply pumps) are ATPases that use the energy of ATP hydrolysis to move ions or small molecules across a membrane *against* a chemical concentration gradient, an electric potential, or both. This process, referred to as **active transport**, is an example of a coupled chemical reaction (Chapter 2). In this case, transport of ions or small molecules “uphill” against an electrochemical gradient, which requires energy, is coupled to the hydrolysis of ATP, which releases energy. The overall reaction—ATP hydrolysis and the “uphill” movement of ions or small molecules—is energetically favorable.

Channels transport water, specific ions, or hydrophilic small molecules across membranes *down* their concentration or electric potential gradients. Because this process requires transport proteins but not energy, it is sometimes referred to as “passive transport” or “facilitated diffusion,” but it is more properly called **facilitated transport**. Channels form a hydrophilic “tube” or passageway across the membrane through which multiple water molecules or ions move simultaneously, single file, at a very rapid rate. Some channels are open much of the time; these are referred to as *nongated* channels. Most ion channels, however, open only in response to specific chemical or electric signals. These are referred to as *gated* channels because a protein “gate” alternatively blocks the channel or moves out of the way to open the channel (see Figure 11-2). Channels, like all transport proteins, are very selective for the type of molecule they transport.

Transporters (also called carriers) move a wide variety of ions and molecules across cell membranes, but at a much slower rate than channels. Three types of transporters have been identified. *Uniporters* transport a single type of molecule *down* its concentration gradient. Glucose and amino acids cross the plasma membrane into most mammalian cells with the aid of uniporters. Collectively, channels and uniporters are sometimes called *facilitated transporters*, indicating movement down a concentration or electrochemical gradient.

In contrast, *antiporters* and *symporters* couple the movement of one type of ion or molecule *against* its concentration gradient with the movement of one or more different ions *down* its concentration gradient, in the same (symporter) or different (antiporter) directions. These proteins often are called *cotransporters*, referring to their ability to transport two or more different solutes simultaneously.

Like ATP pumps, cotransporters mediate coupled reactions in which an energetically unfavorable reaction (i.e., uphill movement of one type of molecule or ion) is coupled to an energetically favorable reaction (i.e., the downhill movement of another). Note, however, that the nature of the energy-supplying reaction driving active transport by these two classes of proteins differs. ATP pumps use energy from hydrolysis of ATP, whereas cotransporters use the energy stored in an electrochemical gradient. This latter process sometimes is referred to as *secondary active transport*.

Conformational changes are essential to the function of all transport proteins. ATP-powered pumps and transporters undergo a cycle of conformational change exposing a binding site (or sites) to one side of the membrane in one conformation and

FIGURE 11-3 Multiple membrane transport proteins function together in the plasma membrane of metazoan cells. Gradients are indicated by triangles with the tip pointing toward lower concentration. The Na⁺/K⁺ ATPase in the plasma membrane uses energy released by ATP hydrolysis to pump Na⁺ out of the cell and K⁺ inward; this creates a concentration gradient of Na⁺ that is greater outside the cell than inside and one of K⁺ that is greater inside than outside. Movement of positively charged K⁺ ions out of the cell through membrane K⁺ channel proteins creates an electric potential across the plasma membrane—the cytosolic face is negative with respect to the extracellular face. A Na⁺/lysine transporter, a typical sodium/amino acid cotransporter, moves 2 Na⁺ ions together with one lysine from the extracellular medium into the cell. “Uphill” movement of the amino acid is powered by “downhill” movement of Na⁺ ions, powered both by the outside-greater-than-inside Na⁺ concentration gradient and by the negative potential on the inside of the cell membrane, which attracts the positively charged Na⁺ ions. The ultimate source of the energy to power amino acid uptake comes from the ATP hydrolyzed by the Na⁺/K⁺ ATPase, since this pump creates both the Na⁺ ion concentration gradient and, via the K⁺ channels, the membrane potential, which together power influx of Na⁺ ions.

to the other side in a second conformation. Because each such cycle results in movement of only one (or a few) substrate molecules, these proteins are characterized by relatively slow rates of transport ranging from 10⁰ to 10⁴ ions or molecules per second (see Figure 11-2). Most ion channels shuttle between a closed state and an open state, but many ions can pass through an open channel without any further conformational change. For this reason, channels are characterized by very fast rates of transport, up to 10⁸ ions per second.

Frequently, several different types of transport proteins work in concert to achieve a physiological function. An example is seen in Figure 11-3, where an ATPase pumps Na⁺ out of the cell and K⁺ ions inward; this pump, which is found in virtually all metazoan cells, establishes the oppositely directed concentration gradients of Na⁺ and K⁺ ions across the plasma membrane (relatively high concentrations of K⁺ inside and Na⁺ outside of cells) that are used to power the import of amino acids. The human genome encodes hundreds of different types of transport proteins that use the energy stored across the plasma membrane in the Na⁺ concentration gradient and its associated electric potential to transport a wide variety of molecules into cells against their concentration gradients.

TABLE 11-1 Mechanisms for Transporting Ions and Small Molecules Across Cell Membranes

Property	Simple Diffusion	Facilitated Transport	Active Transport	Cotransport*
Requires specific protein	—	+	+	+
Solute transported against its gradient	—	—	+	+
Coupled to ATP hydrolysis	—	—	+	—
Driven by movement of a cotransported ion down its gradient	—	—	—	+
Examples of molecules transported	O ₂ , CO ₂ , steroid hormones, many drugs	Glucose and amino acids (uniporters); ions and water (channels)	Ions, small hydrophilic molecules, lipids (ATP-powered pumps)	Glucose and amino acids (symporters); various ions and sucrose (antiporters)

*Also called *secondary active transport*.

Table 11-1 summarizes the four mechanisms by which small molecules and ions are transported across cellular membranes. In the next section we consider some of the simplest membrane transport proteins, those responsible for the transport of glucose and water.

KEY CONCEPTS of Section 11.1

Overview of Transmembrane Transport

- Cellular membranes regulate the traffic of molecules and ions into and out of cells and their organelles. The rate of simple diffusion of a substance across a membrane is proportional to its concentration gradient and hydrophobicity.
- With the exception of gases (e.g., O₂ and CO₂) and small, uncharged, water-soluble molecules, most molecules cannot diffuse across a pure phospholipid bilayer at rates sufficient to meet cellular needs.
- Membrane transport proteins provide a hydrophilic passageway for molecules and ions to travel through the hydrophobic interior of a membrane.
- Three classes of transmembrane proteins mediate transport of ions, sugars, amino acids, and other metabolites across cell membranes: ATP-powered pumps, channels, and transporters (see Figure 11-2).
- ATP-powered pumps couple the movement of a substrate *against* its concentration gradient to ATP hydrolysis, a process known as active transport.
- Channels form a hydrophilic “tube” through which water or ions move *down* a concentration gradient, a process known as facilitated transport or facilitated diffusion.

- Transporters fall into three groups: Uniporters transport a molecule down its concentration gradient (facilitated transport); symporters and antiporters couple movement of a substrate against its concentration gradient to the movement of a second substrate down its concentration gradient, a process known as secondary active transport or cotransport (see Table 11-1).
- Conformational changes are essential to the function of all membrane transport proteins; speed of transport depends on the number of substrates that can pass through a protein at once.

11.2 Facilitated Transport of Glucose and Water

Most animal cells utilize glucose as a substrate for ATP production; they usually employ a glucose uniporter to take up glucose from the blood or other extracellular fluid. Many cells utilize channel-like membrane transport proteins called aquaporins to increase the rate of water movement across their surface membranes. Here, we discuss the structure and function of these and other facilitated transporters.

Uniport Transport Is Faster and More Specific than Simple Diffusion

The protein-mediated transport of a single type of molecule, such as glucose or other small hydrophilic molecules, down a concentration gradient across a cellular membrane is

known as **uniport**. Several features distinguish uniport from simple diffusion:

1. The rate of substrate movement by uniporters is far higher than simple diffusion through a pure phospholipid bilayer.
2. Because the transported molecule never enters the hydrophobic core of the phospholipid bilayer, its partition coefficient K is irrelevant.
3. Transport occurs via a limited number of uniporter molecules. Consequently, there is a maximum transport rate $V_{\max}$ that depends on the number of uniporters in the membrane. $V_{\max}$ is achieved when the concentration gradient across the membrane is very large and each uniporter is working at its maximal rate.
4. Transport is reversible, and the direction of transport will change if the direction of the concentration gradient changes.
5. Transport is specific. Each uniporter transports only a single type of molecule or a single group of closely related molecules. A measure of the affinity of a transporter for its substrate is K_m , which is the concentration of substrate at which transport is half maximal.

These properties also apply to transport mediated by the other classes of proteins depicted in Figure 11-2.

One of the best-understood uniporters is the glucose transporter called *GLUT1* found in the plasma membrane of most mammalian cells. *GLUT1* is especially abundant in the erythrocyte plasma membrane. Because these cells have a single membrane and no nucleus or other internal organelles (see Figure 10-7a), the properties of *GLUT1* and many other transport proteins from mature erythrocytes have been extensively studied. The simplified structure of these cells makes isolating and purifying a transport protein a fairly straightforward procedure.

Figure 11-4 shows that glucose uptake by erythrocytes and liver cells exhibits kinetics similar to that of a simple enzyme-catalyzed reaction involving a single substrate. The kinetics of transport reactions mediated by other types of proteins are more complicated than those for uniporters. Nonetheless, all protein-assisted (facilitated) transport reactions occur faster than simple diffusion across the bilayer, are substrate-specific, and exhibit a maximal rate ($V_{\max}$).

The Low K_m of the GLUT1 Uniporter Enables It to Transport Glucose into Most Mammalian Cells

Like other uniporters, *GLUT1* alternates between two conformational states: in one, a glucose-binding site faces the outside of the cell; in the other, a glucose-binding site faces the cytosol. Since the glucose concentration usually is higher in the extracellular medium (blood, in the case of erythrocytes) than in the cell, the *GLUT1* uniporter generally catalyzes the net import of glucose from the extracellular medium

EXPERIMENTAL FIGURE 11-4 Cellular uptake of glucose mediated by GLUT proteins exhibits simple enzyme kinetics.

The initial rate of glucose uptake, v (measured as micromoles per milliliter of cells per hour), in the first few seconds is plotted as a percentage of the maximum rate, $V_{\max}$, against increasing glucose concentration in the extracellular medium. In this experiment, the initial concentration of glucose in the cells is always zero. Both *GLUT1*, expressed by erythrocytes, and *GLUT2*, expressed by liver cells, catalyze glucose uptake (burgundy and tan curves). Like enzyme-catalyzed reactions, *GLUT*-facilitated uptake of glucose exhibits a maximum rate ($V_{\max}$). The K_m is the concentration at which the rate of glucose uptake is half maximal. *GLUT2*, with a K_m of about 20 mM (not shown), has a much lower affinity for glucose than *GLUT1*, with a K_m of about 1.5 mM.

into the cell. Figure 11-5 depicts the sequence of events occurring during the unidirectional transport of glucose from the cell exterior inward to the cytosol. *GLUT1* also can catalyze the net export of glucose from the cytosol to the extracellular medium, when the glucose concentration is higher inside the cell than outside.

The kinetics of the unidirectional transport of glucose from the outside of a cell inward via *GLUT1* can be described by the same type of equation used to describe a simple enzyme-catalyzed chemical reaction. For simplicity, let's assume that the substrate glucose, S , is present initially only on the outside of the cell; this can be achieved by first incubating the cells in a medium lacking glucose so their internal stores are depleted. In this case, we can write

where $S_{\text{out}} - \text{GLUT1}$ represents *GLUT1* in the outward-facing conformation with a bound glucose. This equation is similar to the one describing the path of a simple enzyme-catalyzed reaction where the protein binds a single substrate and then transforms it into a different molecule. Here, however, no chemical modification occurs to the *GLUT1*-bound sugar; rather, it is moved across a cellular membrane. Nonetheless, the kinetics of this transport reaction are similar to those of simple enzyme-catalyzed reactions, and we can use the same

FIGURE 11-5 Model of uniport transport by GLUT1. In one conformation, the glucose-binding site faces outward; in the other, the binding site faces inward. Binding of glucose to the outward-facing site (step **1**) triggers a conformational change in the transporter such that the binding site now faces inward toward the cytosol (step **2**). Glucose then is released to the inside of the cell (step **3**). Finally, the

transporter undergoes the reverse conformational change, regenerating the outward-facing binding site (step **4**). If the concentration of glucose is higher inside the cell than outside, the cycle will work in reverse (step **4** → step **1**), resulting in net movement of glucose out of the cell. The actual conformational changes are probably smaller than those depicted here.

derivation as that of the Michaelis-Menten equation in Chapter 3 to derive the following expression for v_0 , the initial transport rate for S into the cell catalyzed by GLUT1:

$$v_0 = \frac{V_{\max}}{1 + \frac{K_m}{C}} \quad (11-1)$$

where C is the concentration of S_{out} (initially, the concentration of $S_{\text{in}} = 0$). $V_{\max}$, the rate of transport when all molecules of GLUT1 contain a bound S, occurs at an infinitely high S_{out} concentration. The lower the value of K_m , the more tightly the substrate binds to the transporter. Equation 11-1 describes the curve for glucose uptake by erythrocytes shown in Figure 11-4 as well as similar curves for other uniporters.

For GLUT1 in the human erythrocyte membrane, the K_m for glucose transport is 1.5 mM. Thus when the extracellular glucose concentration is 1.5 mM, roughly half the GLUT1 transporters with outward-facing binding sites will have a bound glucose and transport will occur at 50 percent of the maximal rate. Since blood glucose is normally 5 mM, the erythrocyte glucose transporter usually is functioning at 77 percent of its maximal rate, as can be seen from Equation 11-1. The GLUT1 transporter (or the very similar GLUT3 glucose transporter) is expressed by all body cells that need to take up glucose from the blood continuously at high rates; the rate of glucose uptake by such cells will remain high regardless of small changes in the concentration of blood glucose, because the blood concentration remains much higher than the K_m and the intracellular glucose concentration is kept low by metabolism.

In addition to glucose, the isomeric sugars D-mannose and D-galactose, which differ from D-glucose in their configuration at only one carbon atom, are transported by GLUT1 at measurable rates. However, the K_m for glucose (1.5 mM) is much lower than it is for D-mannose (20 mM) or D-galactose (30 mM). Thus GLUT1 is quite specific, having a much higher affinity (indicated by a lower K_m) for the normal substrate D-glucose than for other substrates.

GLUT1 accounts for 2 percent of the protein in the plasma membrane of erythrocytes. After glucose is transported into the erythrocyte, it is rapidly phosphorylated, forming glucose 6-phosphate, which cannot leave the cell. Because this reaction, the first step in the metabolism of glucose (see Figure 12-3), is rapid and occurs at a constant rate, the intracellular concentration of glucose is kept low even when glucose is imported from the extracellular environment. Consequently the concentration gradient of glucose (outside greater than inside the cell) is maintained sufficiently high to support continuous, rapid import of additional glucose molecules and provide sufficient glucose for cellular metabolism.

The Human Genome Encodes a Family of Sugar-Transporting GLUT Proteins

The human genome encodes at least 14 highly homologous GLUT proteins, GLUT1–GLUT14, that are all thought to contain 12 membrane-spanning α helices, suggesting that they evolved from a single ancestral transport protein. Although no three-dimensional structure of any GLUT protein is available, detailed biochemical studies on GLUT1 have shown that the amino acid residues in the transmembrane α helices are predominantly hydrophobic; several helices, however, bear amino acid residues (e.g., serine, threonine, asparagine, and glutamine) whose side chains can form hydrogen bonds with the hydroxyl groups on glucose. These residues are thought to form the inward-facing and outward-facing glucose-binding sites in the interior of the protein (see Figure 11-5).

The structures of all GLUT isoforms are thought to be quite similar, and all transport sugars. Nonetheless, their differential expression in various cell types, the regulation of the number of GLUT transporters on cell surfaces, and isoform-specific functional properties enable different body cells to regulate glucose metabolism differently and at the same time allow a constant concentration of glucose in the blood to be maintained. For instance, GLUT3 is found in neuronal cells of the brain. Neurons depend on a constant influx of glucose for metabolism, and the low K_m of GLUT3

for glucose ($K_m = 1.5$ mM), like that of GLUT1, ensures that these cells incorporate glucose from brain extracellular fluids at a high and constant rate.

GLUT2, expressed in liver cells and the insulin-secreting islet β cells of the pancreas, has a K_m of ~ 20 mM, about 13 times higher than the K_m of GLUT1. As a result, when blood glucose rises after a meal from its basal level of 5 mM to 10 mM or so, the rate of glucose influx will almost double in GLUT2-expressing cells, whereas it will increase only slightly in GLUT1-expressing cells (see Figure 11-4). In liver, the “excess” glucose brought into the cell is stored as the polymer glycogen. In islet β cells, the rise in glucose triggers secretion of the hormone insulin (see Figure 16-38), which in turn lowers blood glucose by increasing glucose uptake and metabolism in muscle and by inhibiting glucose production in liver (see Figure 15-38). Indeed, cell-specific inactivation of GLUT2 in pancreatic β -cells prevents glucose-stimulated insulin secretion and in liver cells (hepatocytes) disrupts the regulated expression of glucose-sensitive genes.

Another GLUT isoform, GLUT4, is expressed only in fat and muscle cells, the cells that respond to insulin by increasing their uptake of glucose, thereby removing glucose from the blood. In the absence of insulin, GLUT4 resides in intracellular membranes, not the plasma membrane, and is unable to facilitate glucose uptake from the extracellular fluid. By a process detailed in Figure 16-39, insulin causes these GLUT4-rich internal membranes to fuse with the plasma membrane, increasing the number of GLUT4 molecules present on the cell surface and thus the rate of glucose uptake. This is one principal mechanism by which insulin lowers blood glucose; defects in the movement of GLUT4 to the plasma membrane is one of the causes of adult onset, or type II, diabetes, a disease marked by continuously high blood glucose.

GLUT5 is the only GLUT protein with a high specificity (preference) for fructose; its principal site of expression is the apical membrane of intestinal epithelial cells, where it transports dietary fructose from the intestinal lumen to inside the cells.

Transport Proteins Can Be Studied Using Artificial Membranes and Recombinant Cells

There are a variety of approaches for studying the intrinsic properties of transport proteins, such as defining the V_{max} and K_m parameters and identifying key residues responsible for binding. Most cellular membranes contain many different types of transport proteins but a relatively low concentration of any particular one, making functional studies of a single protein difficult. To facilitate such studies, researchers use two approaches for enriching a transport protein of interest so that it predominates in the membrane: purification and reconstitution into artificial membranes, and overexpression in recombinant cells.

In the first approach, a specific transport protein is extracted from its membrane with detergent and purified. Although transport proteins can be isolated from membranes and purified, their functional properties (i.e., their role in the

movement of substrates across membranes) can be studied only when they are associated with a membrane. Thus, the purified protein is usually reincorporated into pure phospholipid bilayer membranes, such as liposomes (see Figure 10-3), across which substrate transport can be readily measured. One good source of GLUT1 is erythrocyte membranes. Another is recombinant cultured mammalian cells expressing a GLUT1 transgene, often one expressing a modified GLUT1 that contains an epitope tag (a portion of a molecule to which a monoclonal antibody [see Chapter 9] can bind) fused to its N- or C-terminus. All of the integral proteins in either of these two types of cells can be solubilized by a non-ionic detergent, such as octylglucoside. The glucose uniporter GLUT1 can be purified from the solubilized mixture by antibody affinity chromatography (Chapter 3) on a column containing either a GLUT1-specific monoclonal antibody or an antibody specific for the epitope tag, and then incorporated into liposomes made of pure phospholipids.

Alternatively, the gene encoding a specific transport protein can be expressed at high levels in a cell type that normally does not express it. The difference in transport of a substance by the transfected and by control nontransfected cells will be due to the expressed transport protein. In these systems, the functional properties of the various membrane proteins can be examined without ambiguity caused, for instance, by partial protein denaturation during isolation and purification procedures. As an example, overexpressing GLUT1 in lines of cultured fibroblasts increases severalfold their rate of uptake of glucose, and expression of mutant GLUT1 proteins with specific amino acid alterations can identify residues important for substrate binding.

Osmotic Pressure Causes Water to Move Across Membranes

Movement of water into and out of cells is an important feature of the life of microorganisms, plants, and animals. Aquaporins are a family of membrane proteins that allow water and a few other small uncharged molecules, such as glycerol, to cross biomembranes efficiently. But before discussing these transport proteins, we need to review osmosis, the force that powers the movement of water across membranes.

Water spontaneously moves “downhill” across a semipermeable membrane from a solution of low solute concentration (relatively higher water concentration) to one of high solute concentration (relatively lower water concentration), a process termed osmosis, or osmotic flow. In effect, osmosis is equivalent to “diffusion” of water across the semipermeable membrane. Osmotic pressure is defined as the hydrostatic pressure required to stop the net flow of water across a membrane separating solutions of different water concentrations (Figure 11-6). In other words, the osmotic pressure balances the entropy-driven thermodynamic force of the water concentration gradient. In this context, the “membrane” may be a layer of cells or a plasma membrane that is permeable to water but not to the solutes. The osmotic pressure is directly proportional to the difference in the concentration

FIGURE 11-6 Osmotic pressure. Solutions A and B are separated by a membrane that is permeable to water but impermeable to all solutes. If C_B (the total concentration of solutes in solution B) is greater than C_A , water will tend to flow across the membrane from solution A to solution B. The osmotic pressure π between the solutions is the hydrostatic pressure that would have to be applied to solution B to prevent this water flow. From the van't Hoff equation, osmotic pressure is given by $\pi = RT(C_B - C_A)$, where R is the gas constant and T is the absolute temperature.

of the total number of solute molecules on each side of the membrane. For example, a 0.5 M NaCl solution is actually 0.5 M Na^+ ions and 0.5 M Cl^- ions and has the same osmotic pressure as a 1 M solution of glucose or sucrose.

The movement of water across the plasma membrane determines the volume of individual cells, which must be regulated to avoid damage to the cell. Small changes in extracellular osmotic conditions cause most animal cells to swell or shrink rapidly. When placed in a **hypotonic** solution (i.e., one in which the concentration of solutes is *lower* than in the cytosol), animal cells swell owing to the osmotic flow of water inward. Conversely, when placed in a **hypertonic** solution (i.e., one in which the concentration of solutes is *higher* than in the cytosol), animal cells shrink as cytosolic water leaves the cell by osmotic flow. Consequently, cultured animal cells must be maintained in an **isotonic** medium, which has a solute concentration and thus osmotic strength similar to that of the cell cytosol.

In vascular plants, water and minerals are absorbed from the soil by the roots and move up the plant through conducting tubes (the xylem); water loss from the plant, mainly by evaporation from the leaves, drives this movement of water. Unlike animal cells, plant, algal, fungal, and bacterial cells are surrounded by a rigid cell wall, which resists the expansion of the volume of the cell when the intracellular osmotic pressure increases. Without such a wall, animal cells expand when internal osmotic pressure increases—if that pressure rises too much, the cells will burst like overinflated balloons. Because of the cell wall in plants, the osmotic influx of water that occurs when such cells are placed in a hypotonic solution (even pure water) leads to an increase in intracellular pressure but not in cell volume. In plant cells, the concentration of solutes (e.g.,

sugars and salts) usually is higher in the vacuole (see Figure 9-32) than in the cytosol, which in turn has a higher solute concentration than the extracellular space. The osmotic pressure, called **turgor pressure**, generated from the entry of water into the cytosol and then into the vacuole pushes the cytosol and the plasma membrane against the resistant cell wall. Plant cells can harness this pressure to help them stand upright, and also grow. Cell elongation during growth occurs by a hormone-induced localized loosening of a defined region of the cell wall, followed by influx of water into the vacuole, increasing its size and thus the size of the cell. ■

Although most protozoans (like animal cells) do not have a rigid cell wall, many contain a **contractile vacuole** that permits them to avoid osmotic lysis. A contractile vacuole takes up water from the cytosol and, unlike a plant vacuole, periodically discharges its contents through fusion with the plasma membrane. Thus even though water continuously enters the protozoan cell by osmotic flow, the contractile vacuole prevents too much water from accumulating in the cell and swelling it to the bursting point.

Aquaporins Increase the Water Permeability of Cell Membranes

The natural tendency of water to flow across cell membranes as a result of osmotic pressure raises an obvious question: why don't the cells of fresh-water animals burst in water? For example, frogs lay their eggs in pond water (a hypotonic solution), but frog oocytes and eggs do not swell with water even though their internal salt (mainly KCl) concentration is comparable to that of other cells (~150 mM KCl). These observations were what first led investigators to suspect that the plasma membranes of most cell types, but not frog oocytes, contain water-channel proteins that accelerate the osmotic flow of water. The experimental results shown in Figure 11-7 demonstrate that an aquaporin from the erythrocyte plasma membrane functions as a water channel.

In its functional form, aquaporin is a tetramer of identical 28-kDa subunits (Figure 11-8a). Each subunit contains six membrane-spanning α helices that form a central pore through which water can move in either direction, depending on the osmotic gradient (Figure 11-8b, c). At the center of each monomer, the ~2-nm-long water-selective channel, or pore, is only 0.28 nm in diameter—only slightly larger than the diameter of a water molecule. The molecular sieving properties of the constriction are determined by several conserved hydrophilic amino acid residues whose side-chain and carbonyl groups extend into the middle of the channel and by a relatively hydrophobic wall that lines one side of the channel. Several water molecules move simultaneously through the channel, each molecule sequentially forming specific hydrogen bonds with channel-lining amino acids and displacing another water molecule downstream. Since aquaporins do not undergo conformational changes during water transport, they transport water orders of magnitude faster than GLUT1

VIDEO: Frog Oocyte Expressing Aquaporin Bursts in Hypotonic Solution

EXPERIMENTAL FIGURE 11-7 Expression of aquaporin by frog oocytes increases their permeability to water. Frog oocytes, which normally are impermeable to water and do not express an aquaporin protein, were microinjected with mRNA encoding aquaporin. These photographs show control oocytes (bottom cell in each panel) and microinjected oocytes (top cell in each panel) at the indicated times after transfer from an isotonic salt solution (0.1 M) to a hypotonic salt

solution (0.035 M). The volume of the control oocytes remained unchanged because they are poorly permeable to water. In contrast, the microinjected oocytes expressing aquaporin swelled and then burst because of an osmotic influx of water, indicating that aquaporin is a water-channel protein. [Courtesy of Gregory M. Preston and Peter Agre, Johns Hopkins University School of Medicine. See L. S. King, D. Kozono, and P. Agre, 2004, *Nat. Rev. Mol. Cell Biol.* **5**:687–698.]

FIGURE 11-8 Structure of the water-channel protein aquaporin. (a) Structural model of the tetrameric protein comprising four identical subunits. Each subunit forms a water channel, as seen in this view looking down on the protein from the exoplasmic side. One of the monomers is shown with a molecular surface in which the pore entrance can be seen. (b) Schematic diagram of the topology of a single aquaporin subunit in relation to the membrane. Three pairs of homologous transmembrane α helices (A and A', B and B', and C and C') are oriented in the opposite direction with respect to the membrane and are connected by two hydrophilic loops containing short non-membrane-spanning helices and conserved asparagine (N) residues. The loops bend into the cavity formed by the six transmembrane helices, meeting in the middle to form part of the water-selective

gate. (c) Side view of the pore in a single aquaporin subunit in which several water molecules (red oxygens and white hydrogens) are seen within the 2-nm-long water-selective gate that separates the water-filled cytosolic and extracellular vestibules. The gate contains highly conserved arginine and histidine residues, as well as the two asparagine residues whose side chains form hydrogen bonds with transported water molecules. (Key gate residues, including the two asparagines, are highlighted in blue.) Transported water molecules also form hydrogen bonds to the main-chain carbonyl group of a cysteine residue. The arrangement of these hydrogen bonds and the narrow pore diameter of 0.28 nm prevent passage of protons (i.e., H_3O^+) or other ions. [After H. Sui et al., 2001, *Nature* **414**:872. See also T. Zeuthen, 2001, *Trends Biochem. Sci.* **26**:77, and K. Murata et al., 2000, *Nature* **407**:599.]

transports glucose. The formation of hydrogen bonds between the oxygen atom of water and the amino groups of two amino acid side chains ensures that only uncharged water (i.e., H_2O , but not H_3O^+) passes through the channel; the orientations of the water molecules in the channel prevent protons from jumping from one to the next and thus prevent the net movement of protons through the channel. As a consequence ionic gradients are maintained across membranes even when water is flowing across them through aquaporins.

Mammals express a family of aquaporins; 11 such genes are known in humans. Aquaporin 1 is expressed in abundance in erythrocytes, and the homologous aquaporin 2 is found in the kidney epithelial cells that resorb water from the urine, thus controlling the amount of water in the body. The activity of aquaporin 2 is regulated by vasopressin, also called antidiuretic hormone. The regulation of the activity of aquaporin 2 in resting kidney cells resembles that of GLUT4 in fat and muscle in that when its activity is not required, when the cells are in their resting state and water is excreted to form urine, aquaporin 2 is sequestered in intracellular vesicle membranes and so is unable to mediate water import into the cell. When the polypeptide hormone vasopressin binds to the cell-surface vasopressin receptor, it activates a signaling pathway using cAMP as the intracellular signal (detailed in Chapter 15) that causes these aquaporin 2-containing vesicles to fuse with the plasma membrane, increasing the rate of water uptake and its return into the circulation instead of the urine. Inactivating mutations in either the vasopressin receptor or the aquaporin 2 gene cause *diabetes insipidus*, a disease marked by excretion of large volumes of dilute urine. This finding demonstrates that the level of aquaporin 2 is rate limiting for water resorption from urine being formed by the kidney. ■

Other members of the aquaporin family transport hydroxyl-containing molecules such as glycerol rather than water. Human aquaporin 3, for instance, transports glycerol and is similar in amino acid sequence and structure to the *Escherichia coli* glycerol transport protein GlpF.

KEY CONCEPTS of Section 11.2

Facilitated Transport of Glucose and Water

- Protein-catalyzed transport of biological solutes across a membrane occurs much faster than simple diffusion, exhibits a V_{max} when the limited number of transporter molecules are saturated with substrate, and is highly specific for substrate (see Figure 11-4).
- Uniport proteins, such as the glucose transporters (GLUTs), are thought to shuttle between two conformational states, one in which the substrate-binding site faces outward and one in which the binding site faces inward (see Figure 11-5).
- All members of the GLUT protein family transport sugars and have similar structures. Differences in their K_m values,

expression in different cell types, and substrate specificities are important for proper sugar metabolism in the body.

- Two common experimental systems for studying the functions of transport proteins are liposomes containing a purified transport protein and cells transfected with the gene encoding a particular transport protein.
- Most biological membranes are semipermeable, more permeable to water than to ions or most other solutes. Water moves by osmosis across membranes from a solution of lower solute concentration to one of higher solute concentration.
- The rigid cell wall surrounding plant cells prevents their swelling and leads to generation of turgor pressure in response to the osmotic influx of water.
- Aquaporins are water-channel proteins that specifically increase the permeability of biomembranes to water (see Figure 11-8).
- Aquaporin 2 in the plasma membrane of certain kidney cells is essential for resorption of water from urine being formed; the absence of aquaporin 2 leads to the medical condition diabetes insipidus.

11.3 ATP-Powered Pumps and the Intracellular Ionic Environment

In previous sections, we focused on transport proteins that move molecules down their concentration gradients (facilitated transport). Here we focus our attention on a major class of proteins—the ATP-powered pumps—that use the energy released by hydrolysis of the terminal phosphoanhydride bond of ATP to transport ions and various small molecules across membranes *against* their concentration gradients. All ATP-powered pumps are transmembrane proteins with one or more binding sites for ATP located on subunits or segments of the protein that always face the cytosol. These proteins commonly are called *ATPases* and they normally do not hydrolyze ATP into ADP and P_i unless ions or other molecules are simultaneously transported. Because of this tight *coupling* between ATP hydrolysis and transport, the energy stored in the phosphoanhydride bond is not dissipated as heat but rather is used to move ions or other molecules uphill against an electrochemical gradient.

There are Four Main Classes of ATP-Powered Pumps

The general structures of the four classes of ATP-powered pumps are depicted in Figure 11-9, with specific examples in each class listed below the figure. Note that the members of three of the classes (P, F, and V) only transport ions, as do some members of the fourth class, the ABC superfamily. Most members of the ABC superfamily transport small molecules such as amino acids, sugars, peptides, lipids, and other small molecules including many types of drugs.

FIGURE 11-9 The four classes of ATP-powered transport proteins. The locations of specific pumps are indicated below each class. P-class pumps are composed of two catalytic α subunits, which become phosphorylated as part of the transport cycle. Two β subunits, present in some of these pumps, may regulate transport. Only one α and one β subunit are depicted. V-class and F-class pumps do not form phosphoprotein intermediates and almost all transport only protons. Their structures are similar and contain similar proteins, but none of their subunits are related to those of P-class pumps. V-class pumps couple ATP hydrolysis to transport of protons against a concentration

gradient, whereas F-class pumps normally operate in the reverse direction to utilize energy in a proton concentration or voltage gradient to synthesize ATP. All members of the large ABC superfamily of proteins contain two transmembrane (T) domains and two cytosolic ATP-binding (A) domains, which couple ATP hydrolysis to solute movement. These core domains are present as separate subunits in some ABC proteins (depicted here) but are fused into a single polypeptide in other ABC proteins. [See T. Nishi and M. Forgac, 2002, *Nature Rev. Mol. Cell Biol.* **3**:94; C. Toyoshima et al., 2000, *Nature* **405**:647; D. McIntosh, 2000, *Nature Struct. Biol.* **7**:532; and T. Elston, H. Wang, and G. Oster, 1998, *Nature* **391**:510.]

All *P-class ion pumps* possess two identical catalytic α subunits, each of which contains an ATP-binding site. Most also have two smaller β subunits that usually have regulatory functions. During transport, at least one of the α subunits becomes phosphorylated (hence the name “P” class), and the transported ions move through the phosphorylated subunit. The amino acid sequences around the phosphorylated residues are homologous in different pumps. This class includes the Na^+/K^+ ATPase in the plasma membrane, which generates the low cytosolic Na^+ and high cytosolic K^+ concentrations typical of animal cells (see Figure 11-3). Certain Ca^{2+} ATPases pump Ca^{2+} ions out of the cytosol into the external medium; others pump Ca^{2+} from the cytosol into the endoplasmic reticulum or into the specialized ER called the **sarcoplasmic reticulum** that is found in muscle cells. Another member of the P class, found in acid-secreting cells of the mammalian stomach, transports protons (H^+ ions) out of and K^+ ions into the cell.

The structures of *V-class* and *F-class ion pumps* are similar to one another but unrelated to, and more complicated than, P-class pumps. V- and F-class pumps contain several different

transmembrane and cytosolic subunits. Virtually all known V and F pumps transport only protons and do so in a process that does not involve a phosphoprotein intermediate. V-class pumps generally function to generate the low pH of plant vacuoles and of lysosomes and other acidic vesicles in animal cells by pumping protons from the cytosolic to the exoplasmic face of the membrane against a proton electrochemical gradient. In contrast, the H^+ pumps that generate and maintain the plasma membrane electric potential in plant, fungal, and many bacterial cells belong to the P-class of proton pumps.

F-class pumps are found in bacterial plasma membranes and in mitochondria and chloroplasts. In contrast to V-class pumps, they generally function as reverse proton pumps, in which the energy released by the energetically favored movement of protons from the exoplasmic to the cytosolic face of the membrane *down* the proton electrochemical gradient is used to power the energetically unfavorable synthesis of ATP from ADP and P_i . Because of their importance in ATP synthesis in chloroplasts and mitochondria, F-class proton pumps, commonly called ATP synthases, are treated separately in Chapter 12 (Cellular Energetics).

The final class of ATP-powered pumps is a large family of multiple members that are more diverse in function than those of the other classes. Referred to as the ABC (ATP-binding cassette) **superfamily**, this class includes several hundred different transport proteins found in organisms ranging from bacteria to humans. As detailed below, some of these transport proteins were first identified as multidrug-resistance proteins that, when overexpressed in cancer cells, export anticancer drugs and render tumors resistant to their action. Each ABC protein is specific for a single substrate or group of related substrates, which may be ions, sugars, amino acids, phospholipids, cholesterol, peptides, polysaccharides, or even proteins. All ABC transport proteins share a structural organization consisting of four “core” domains: two transmembrane (T) domains, forming the passageway through which transported molecules cross the membrane, and two cytosolic ATP-binding (A) domains. In some ABC proteins, mostly those in bacteria, the core domains are present in four separate polypeptides; in others, the core domains are fused into one or two multidomain polypeptides.

ATP-Powered Ion Pumps Generate and Maintain Ionic Gradients Across Cellular Membranes

The specific ionic composition of the cytosol usually differs greatly from that of the surrounding extracellular fluid. In virtually all cells—including microbial, plant, and animal cells—the cytosolic pH is kept near 7.2 *regardless* of the extracellular pH. In the most extreme case, there is a million-fold difference in H^+ concentration between the pH of the cytosol of the epithelial cells lining the stomach and the pH of the stomach contents after a meal. Also, the cytosolic concentration of K^+ is much higher than that of Na^+ . In both invertebrates and vertebrates the concentration of K^+ is 20–40 times higher in the cytosol than in the blood, while the concentration of Na^+ is 8–12 times lower in the cytosol than in the blood (Table 11-2). Some Ca^{2+} in the cytosol is bound to the negatively charged groups in ATP and in proteins and other molecules, but it is the concentration of unbound (or “free”) Ca^{2+} that is critical to its functions in signaling pathways and muscle contraction. The concentration of free Ca^{2+} in the cytosol is generally less than 0.2 micromolar (2×10^{-7} M), a thousand or more times lower than that in the blood. Plant cells and many microorganisms maintain similarly high cytosolic concentrations of K^+ and low concentrations of Ca^{2+} and Na^+ even if the cells are cultured in very dilute salt solutions.

The ion pumps discussed in this section are largely responsible for establishing and maintaining the usual ionic gradients across the plasma and intracellular membranes. In carrying out this task, cells expend considerable energy. For example, up to 25 percent of the ATP produced by nerve and kidney cells is used for ion transport, and human erythrocytes consume up to 50 percent of their available ATP for this purpose; in both cases, most of this ATP is used to power the Na^+/K^+ pump (see Figure 11-3). The resultant Na^+ and K^+ gradients in nerve cells are essential for their

TABLE 11-2 Typical Intracellular and Extracellular Ion Concentrations

Ion	Cell (mM)	Blood (mM)
Squid Axon (invertebrate)*		
K^+	400	20
Na^+	50	440
Cl^-	40–150	560
Ca^{2+}	0.0003	10

Mammalian Cell (vertebrate)		
K^+	139	4
Na^+	12	145
Cl^-	4	116
HCO_3^-	12	29
X^-	138	9
Mg^{2+}	0.8	1.5
Ca^{2+}	<0.0002	1.8

*The large nerve axon of the squid has been widely used in studies of the mechanism of conduction of electric impulses.

[†] X^- represents proteins, which have a net negative charge at the neutral pH of blood and cells.

ability to conduct electric signals rapidly and efficiently, as we detail in Chapter 22. Certain enzymes required for protein synthesis in all cells require a high K^+ concentration and are inhibited by high concentrations of Na^+ ; these would cease to function without the operation of the Na^+/K^+ pump. In cells treated with poisons that inhibit the production of ATP (e.g., 2,4-dinitrophenol in aerobic cells), the pumping stops and the ion concentrations inside the cell gradually approach those of the exterior environment as ions spontaneously move through channels in the plasma membrane down their electrochemical gradients. Eventually poison-treated cells die: partly because protein synthesis requires a high concentration of K^+ ions and partly because in the absence of a Na^+ gradient across the cell membrane, a cell cannot import certain nutrients such as amino acids (see Figure 11-3). Studies on the effects of such poisons provided early evidence for the existence and significance of ion pumps.

Muscle Relaxation Depends on Ca^{2+} ATPases That Pump Ca^{2+} from the Cytosol into the Sarcoplasmic Reticulum

In skeletal muscle cells, Ca^{2+} ions are concentrated and stored in the **sarcoplasmic reticulum (SR)**, a specialized type of endoplasmic reticulum (ER). The release via ion channels of stored Ca^{2+} ions from the SR lumen into the cytosol causes muscle contraction, as discussed in Chapter 17. A P-class Ca^{2+} ATPase located in the SR membrane of skeletal muscle pumps Ca^{2+} from the cytosol back into the lumen of the SR, thereby inducing muscle relaxation.

In the cytosol of muscle cells, the free Ca^{2+} concentration ranges from 10^{-7} M (resting cells) to more than 10^{-6} M (contracting cells), whereas the *total* Ca^{2+} concentration in the SR lumen can be as high as 10^{-2} M. The lumen of the SR contains two abundant proteins, calsequestrin and the so-called high-affinity Ca^{2+} binding protein, each of which binds multiple Ca^{2+} ions at high affinity. By binding much of the Ca^{2+} in the SR lumen these proteins reduce the concentration of “free” Ca^{2+} ions in the SR vesicles. This reduces the Ca^{2+} concentration gradient between the cytosol and the SR lumen and consequently reduces the energy needed to pump Ca^{2+} ions into the SR from the cytosol. The activity of the muscle Ca^{2+} ATPase increases as the free Ca^{2+} concentration in the cytosol rises. In skeletal muscle cells the calcium pump in the SR membrane works in concert with a similar Ca^{2+} pump located

in the plasma membrane to ensure that the cytosolic concentration of free Ca^{2+} in resting muscle remains below $0.1 \mu\text{M}$.

The Mechanism of Action of the Ca^{2+} Pump Is Known in Detail

Because the calcium pump constitutes more than 80 percent of the integral protein in muscle SR membranes, it is easily purified from other membrane proteins and has been studied extensively. Determination of the three-dimensional structure of this protein in several conformational states representing different steps in the pumping process has revealed much about its mechanism of action, and serves as a paradigm for understanding many P-class ATPase pumps.

The current model for the mechanism of action of the Ca^{2+} ATPase in the SR membrane involves multiple conformational states. For simplicity, we group these into E1 states, in which the two binding sites for Ca^{2+} , located in the center of the membrane-spanning domain, face the cytosol, and E2 states, in which these binding sites face the exoplasmic face of the membrane, pointing into the lumen of the SR. Coupling of ATP hydrolysis with ion pumping involves several conformational changes in the protein that must occur in a defined order, as shown in Figure 11-10. When the protein is in the E1 conformation, two Ca^{2+} ions bind to two high-affinity binding sites accessible from the cytosolic side; even though the cytosolic Ca^{2+} concentration is low (see Table 11-2), calcium ions still fill these sites.

FIGURE 11-10 Operational model of the Ca^{2+} ATPase in the SR membrane of skeletal muscle cells. Only one of the two catalytic α subunits of this P-class pump is depicted. E1 and E2 are alternative conformations of the protein in which the Ca^{2+} -binding sites are accessible to the cytosolic and exoplasmic (SR lumen) faces, respectively. An ordered sequence of steps, as diagrammed here, is essential for coupling ATP hydrolysis and the transport of Ca^{2+} ions across the

membrane. In the figure, $\sim\text{P}$ indicates a high-energy aspartyl phosphate bond; $-\text{P}$ indicates a low-energy bond. Because the affinity of Ca^{2+} for the cytosolic-facing binding sites in E1 is a thousandfold greater than the affinity of Ca^{2+} for the exoplasmic-facing sites in E2, this pump transports Ca^{2+} unidirectionally from the cytosol to the SR lumen. See the text and Figure 11-11 for more details. [See C. Toyoshima and G. Inesi, 2004, *Ann. Rev. Biochem.* **73**:269–292.]

Next, an ATP binds to a site on the cytosolic surface (step **1**). The bound ATP is hydrolyzed to ADP in a reaction that requires Mg^{2+} , and the liberated phosphate is transferred to a specific aspartate residue in the protein, forming the high-energy acyl phosphate bond denoted by $E1 \sim P$ (step **2**). The protein then undergoes a conformational change that generates $E2$, in which the affinity of the two Ca^{2+} -binding sites is reduced (shown in detail in the next figure) and in which these sites are now accessible to the SR lumen (step **3**). The free energy of hydrolysis of the aspartyl-phosphate bond in $E1 \sim P$ is greater than that in $E2 \sim P$, and this reduction in free energy of the aspartyl-phosphate bond can be said to power the $E1 \rightarrow E2$ conformational change.

The Ca^{2+} ions spontaneously dissociate from the low-affinity sites to enter the SR lumen, because even though the Ca^{2+} concentration there is higher than in the cytosol, it is lower than the K_d for Ca^{2+} binding in the low-affinity state (step **4**). Finally, the aspartyl-phosphate bond is hydrolyzed (step **5**). This dephosphorylation, coupled with subsequent binding of cytosolic Ca^{2+} to the high-affinity $E1$ Ca^{2+} binding sites, stabilizes the $E1$ conformational state relative to $E2$, and can be said to power the $E2 \rightarrow E1$ conformational change (step **6**). Now $E1$ is ready to transport two more Ca^{2+} ions. Thus the cycle is complete and hydrolysis of a phosphoanhydride bond in ATP has powered the pumping of 2 Ca^{2+} ions against its concentration gradient into the SR lumen.

Much structural and biophysical evidence supports the model depicted in Figure 11-10. For instance, the muscle calcium pump has been isolated with phosphate linked to the key aspartate residue, and spectroscopic studies have detected slight alterations in protein conformation during the $E1 \rightarrow E2$ conversion. The two phosphorylated states can also be distinguished biochemically; addition of ADP to phosphorylated $E1$ results in synthesis of ATP, the reverse of step **2** in Figure 11-10, whereas addition of ADP to phosphorylated $E2$ does not. Each principal conformational state of the reaction cycle can also be characterized by a different susceptibility to various proteolytic enzymes such as trypsin.

Figure 11-11 shows the three-dimensional structure of the Ca^{2+} pump in the $E1$ state. As can be seen in the right two panels of part c in the bottom half of the figure, the 10 membrane-spanning α helices in the catalytic subunit form the passageway through which Ca^{2+} ions move. Amino acids in four of these helices form the two high-affinity $E1$ Ca^{2+} -binding sites (Figure 11-11a, left). One site is formed out of negatively charged oxygen atoms from the carboxyl groups (COO^-) of glutamate and aspartate side chains, as well as from water molecules. The other site is formed from side- and main-chain oxygen atoms. Thus, as Ca^{2+} -ions bind to the Ca^{2+} pump they lose the water molecules that normally surround a Ca^{2+} ion in aqueous solution (see Figure 2-7), but these waters are replaced by oxygen atoms with a similar geometry that are part of the transport protein. In contrast, in the $E2$ state (Figure 11-11a, right), several of these binding side chains have moved fractions of a nanometer and are unable to interact with bound Ca^{2+} ions, accounting for the low affinity of the $E2$ state for Ca^{2+} ions.

Binding of Ca^{2+} ions to the Ca^{2+} pump illustrates a general principle of ion binding to channel and transport proteins that we will encounter repeatedly in this chapter: as ions bind they lose most of their waters of hydration but interact with oxygen atoms in the protein that are in a similar geometry to the water oxygens that are bound to the ion in aqueous solution. This reduces the thermodynamic barrier for ion binding to the protein and allows tight binding of the ion even from solutions of relatively low concentrations.

The cytoplasmic region of the Ca^{2+} pump consists of three domains that are well separated from each other in the $E1$ state (Figure 11-11b). Each of these domains is connected to the membrane-spanning helices by short segments of amino acids. Movements of these cytosolic domains during the pumping cycle cause movements of the connecting segments that are transmitted into movements of the attached membrane-spanning α helices. For example, the phosphorylated residue, Asp 351, is located in the P domain. The adenosine moiety of ATP binds to the N domain, but the γ -phosphate of ATP binds to specific residues on the P domain, requiring movements of both the N and P domains. Thus, following ATP and Ca^{2+} binding, the γ phosphate of the bound ATP sits adjacent to the aspartate on the P domain that is to receive the phosphate. Although the precise details of these and other protein conformational changes are not yet clear, the movements of the N and P domains are transmitted by lever-like motions of the connecting segments into rearrangements of several membrane-spanning α helices. These changes are especially apparent in the four helices that contain the two Ca^{2+} -binding sites: the changes prevent the bound Ca^{2+} ions from moving back into the cytosol when released but enable them to dissociate into the exoplasmic space (lumen).

All P-class ion pumps, regardless of which ion they transport, are phosphorylated on a highly conserved aspartate residue during the transport process. As deduced from cDNA sequences, the catalytic α subunits of all the P pumps examined to date have similar amino acid sequences and thus are presumed to have similar arrangements of transmembrane α helices and cytosol-facing A, P, and N domains (see Figure 11-10). These findings strongly suggest that all such proteins evolved from a common precursor although they now transport different ions. This suggestion is borne out by the similarities of the three-dimensional structures of the membrane-spanning segments of the Na^+/K^+ ATPase with that of the Ca^{2+} pump (Figure 11-12); the molecular structures of the three cytoplasmic domains are also very similar. Thus, the operational model in Figure 11-11 is generally applicable to all of the P-class ATP-powered ion pumps.

Calmodulin Regulates the Plasma Membrane Pumps That Control Cytosolic Ca^{2+} Concentrations

As we explain in Chapter 15, in many types of cells in addition to muscle cells, small increases in the concentration of free Ca^{2+} ions in the cytosol trigger a variety of cellular responses.

(a) **E1 state**
High affinity for Ca^{2+}
Two bound Ca^{2+}

E2 state
Low affinity for Ca^{2+}
No bound Ca^{2+}

FIGURE 11-11 Structure of the catalytic α subunit of the muscle Ca^{2+} ATPase. (a) Ca^{2+} -binding sites in the E1 state (left), with two bound calcium ions, and the low-affinity E2 state (right), without bound ions. Side chains of key amino acids are white, and the oxygen atoms on the glutamate and aspartate side chains are red. In the high-affinity E1 conformation, Ca^{2+} ions bind at two sites between helices 4, 5, 6, and 8 inside the membrane. One site is formed out of negatively charged oxygen atoms from glutamate and aspartate side chains and of water molecules (not shown), and the other is formed out of side- and main-chain oxygen atoms. Seven oxygen atoms surround the Ca^{2+} ion in both sites. (b) Three-dimensional model of the protein in the E1 state based on the structure determined by x-ray crystallography. There are 10 transmembrane α helices, four of which (purple) contain residues that participate in Ca^{2+} binding. The cytosolic segment forms

three domains: the nucleotide-binding domain N (blue), the phosphorylation domain P (green), and the actuator domain A (beige) that connects two of the membrane-spanning helices. (c) Models of the pump in the E1 state (left) and E2 state (right). Note the differences between the E1 and E2 states in the conformations of the nucleotide-binding and actuator domains; these movements power the conformational changes of the membrane-spanning α helices (purple) that constitute the Ca^{2+} -binding sites, converting them from one in which the Ca^{2+} -binding sites are accessible to the cytosolic face (E1 state) to one in which the now loosely bound Ca^{2+} ions are accessible to the exoplasmic face (E2 state). [Adapted from C. Toyoshima and H. Nomura, 2002, *Nature* **418**:605–611; C. Toyoshima and G. Inesi, 2004, *Ann. Rev. Biochem.* **73**:269–292; and E. Gouaux and R. MacKinnon, 2005, *Science* **310**:1461.]

In order for Ca^{2+} to function in intracellular signaling, the concentration of Ca^{2+} ions free in the cytosol usually must be kept below 0.1–0.2 μM . Animal, yeast, and probably plant cells express plasma membrane Ca^{2+} ATPases that transport Ca^{2+} out of the cell against its electrochemical gradient. The catalytic α subunit of these P-class pumps is similar in structure and sequence to the α subunit of the muscle SR Ca^{2+} pump.

The activity of plasma membrane Ca^{2+} ATPases is regulated by **calmodulin**, a cytosolic Ca^{2+} -binding protein (see Figure 3-31). A rise in cytosolic Ca^{2+} induces the binding of Ca^{2+} ions to calmodulin, which triggers activation of the Ca^{2+} ATPase. As a result, the export of Ca^{2+} ions from the cell accelerates, quickly restoring the low concentration of free cytosolic Ca^{2+} characteristic of the resting cell.

Na⁺/K⁺ ATPase Maintains the Intracellular Na⁺ and K⁺ Concentrations in Animal Cells

An important P-class ion pump present in the plasma membrane of all animal cells is the Na⁺/K⁺ ATPase. This ion pump is a tetramer of subunit composition $\alpha_2\beta_2$, and shares structural homology with the Ca²⁺ pump (see Figure 11-12). The small, glycosylated β transmembrane polypeptide apparently is not

FIGURE 11-12 Structural comparison of Na⁺/K⁺ ATPase and muscle Ca²⁺ ATPase. Three-dimensional structure of the Na⁺/K⁺ ATPase (gold) compared to that of the muscle Ca²⁺ ATPase (purple), as seen from the cytoplasmic surface. α M1–10 denote the 10 membrane-spanning α -helices of the Na⁺/K⁺ ATPase. [After J. P. North et. al., 2007, *Nature* **450**:1043 and H. Ogawa et. al., 2009, *Proc. Nat'l Acad. Sci. USA* **106**:13742]

involved directly in ion pumping. During the catalytic cycle of the Na⁺/K⁺ ATPase it moves three Na⁺ ions *out* of and two K⁺ ions *into* the cell per ATP molecule hydrolyzed. The mechanism of action of the Na⁺/K⁺ ATPase, outlined in Figure 11-13, is similar to that of the muscle SR calcium pump, except that ions are pumped in *both* directions across the membrane, with each ion moving *against* its concentration gradient. In its E1 conformation, the Na⁺/K⁺ ATPase has three high-affinity Na⁺-binding sites and two low-affinity K⁺-binding sites accessible to the cytosolic surface of the protein. The K_m for binding of Na⁺ to these cytosolic sites is 0.6 mM, a value considerably lower than the intracellular Na⁺ concentration of $\sim$ 12 mM; as a result, Na⁺ ions normally will fully occupy these sites. Conversely, the affinity of the cytosolic K⁺-binding sites is low enough that K⁺ ions, transported inward through the protein, dissociate from E1 into the cytosol despite the high intracellular K⁺ concentration. During the E1 $\rightarrow$ E2 transition, the three bound Na⁺ ions

OVERVIEW ANIMATION: Biological Energy Interconversions

FIGURE 11-13 Operational model of the plasma membrane Na⁺/K⁺ ATPase. Only one of the two catalytic α subunits of this P-class pump is depicted. It is not known whether just one or both subunits in a single ATPase molecule transport ions. Ion pumping by the Na⁺/K⁺ ATPase involves phosphorylation, dephosphorylation, and conformational changes similar to those in the muscle Ca²⁺ ATPase

(see Figure 11-11). In this case, hydrolysis of the E2–P intermediate powers the E2 $\rightarrow$ E1 conformational change and concomitant transport of two K⁺ ions inward. Na⁺ ions are indicated by red circles; K⁺ ions, by purple squares; high-energy acyl phosphate bond, by $\sim$ P; low-energy phosphoester bond, by --P .

become accessible to the exoplasmic face, and simultaneously the affinity of the three Na^+ -binding sites drops. The three Na^+ ions now bound to low-affinity Na^+ sites dissociate one at a time into the extracellular medium despite the high extracellular Na^+ concentration. Transition to the E2 conformation also generates two high-affinity K^+ sites accessible to the exoplasmic face. Because the K_m for K^+ binding to these sites (0.2 mM) is lower than the extracellular K^+ concentration (4 mM), these sites will fill with K^+ ions as the Na^+ ions dissociate. Similarly, during the subsequent E2 $\rightarrow$ E1 transition, the two bound K^+ ions are transported inward and then released into the cytosol.

Certain drugs (e.g., ouabain and digoxin) bind to the exoplasmic domain of the plasma membrane Na^+/K^+ ATPase and specifically inhibit its ATPase activity. The resulting disruption in the Na^+/K^+ balance of cells is strong evidence for the critical role of this ion pump in maintaining the normal K^+ and Na^+ ion concentration gradients. Classic Experiment 11.1, which directly follows this chapter, describes the discovery of this important enzyme, which is required for life.

V-Class H^+ ATPases Maintain the Acidity of Lysosomes and Vacuoles

All V-class ATPases transport only H^+ ions. These proton pumps, present in the membranes of lysosomes, endosomes, and plant vacuoles, function to acidify the lumen of these organelles. The pH of the lysosomal lumen can be measured precisely in living cells by use of particles labeled with a pH-sensitive fluorescent dye. When these particles are added to the extracellular fluid, the cells engulf and internalize them (phagocytosis; see Chapter 17), ultimately transporting them into lysosomes. The lysosomal pH can be calculated from the spectrum of the fluorescence emitted. The DNA encoding a naturally fluorescent protein whose fluorescence depends on the pH can be modified (by adding DNA segments encoding “signal sequences,” detailed in Chapters 13 and 14) such that the protein is targeted to the lysosome lumen; fluorescence measurements can then be used to determine the pH in the organelle lumen. Maintenance of the hundredfold or more proton gradient between the lysosomal lumen (pH $\sim$ 4.5–5.0) and the cytosol (pH $\sim$ 7.0) depends on a V-class ATPase and thus ATP production by the cell. The low lysosomal pH is necessary for optimal function of the many proteases, nucleases, and other hydrolytic enzymes in the lumen; on the other hand, a cytosolic pH of 5 would disrupt the functions of many proteins optimized to act at pH 7 and lead to death of the cell.

Pumping of relatively few protons is required to acidify an intracellular vesicle. To understand why, recall that a solution of pH 4 has an H^+ ion concentration of 10^{-4} moles per liter, or 10^{-7} moles of H^+ ions per milliliter. Since there are 6.02×10^{23} atoms of H per mole (Avogadro’s number), then a milliliter of a pH 4 solution contains 6.02×10^{16} H^+ ions. Thus at pH 4, a primary spherical lysosome with a volume of 4.18×10^{-15} ml (diameter of 0.2 μm) will contain just 252 protons. At pH 7, the same organelle would have an average of only 0.2 protons in its lumen, and thus pumping of only approximately 250 protons is necessary for lysosome acidification.

By themselves, ATP-powered proton pumps cannot acidify the lumen of an organelle (or the extracellular space) because these pumps are *electrogenic*; that is, a net movement of electric charge occurs during transport. Pumping of just a few protons causes a buildup of positively charged H^+ ions on the exoplasmic (inside) face of the organelle membrane. For each H^+ pumped across, a negative ion (e.g., OH^- or Cl^-) will be “left behind” on the cytosolic face, causing a buildup of negatively charged ions there. These oppositely charged ions attract each other on opposite faces of the membrane, generating a charge separation, or electric potential, across the membrane. The lysosome membrane thus functions as a capacitor in an electric circuit, storing opposing charges (anions and cations) on opposite sides of a barrier impermeable to movement of charged particles.

As more and more protons are pumped and build up excess positive charge on the exoplasmic face, the energy required to move additional protons against this rising electric potential gradient increases dramatically and prevents pumping of additional protons long before a significant transmembrane H^+ concentration gradient is established (Figure 11-14a). In fact, this is the way that P-class H^+ pumps generate a cytosol-negative potential across plant and yeast plasma membranes.

In order for an organelle lumen or an extracellular space (e.g., the lumen of the stomach) to become acidic, movement

FIGURE 11-14 Effect of V-class H^+ pumps on H^+ concentration gradients and electric potential gradients across cellular membranes. (a) If an intracellular organelle contains only V-class pumps, proton pumping generates an electric potential across the membrane (cytosol-facing side negative and luminal-side positive) but no significant change in the intraluminal pH. (b) If the organelle membrane also contains Cl^- channels, anions passively follow the pumped protons, resulting in an accumulation of H^+ and Cl^- ions in the lumen (low luminal pH) but no electric potential across the membrane.

of protons must be accompanied either by (1) movement of an equal number of anions (e.g., Cl^-) in the same direction or by (2) movement of equal numbers of a different cation in the opposite direction. The first process occurs in lysosomes and plant vacuoles, whose membranes contain V-class H^+ ATPases and anion channels through which accompanying Cl^- ions move (Figure 11-14b). The second process occurs in the lining of the stomach, which contains a P-class H^+/K^+ ATPase that is not electrogenic and pumps one H^+ outward and one K^+ inward. Operation of this pump is discussed later in the chapter.

The ATP-powered proton pumps in lysosomal and vacuolar membranes have been solubilized, purified, and incorporated into liposomes. As shown in Figure 11-9, these V-class proton pumps contain two discrete domains: a cytosolic hydrophilic domain (V_1) and a transmembrane domain (V_0) with multiple subunits forming each domain. Binding and hydrolysis of ATP by the B subunits in V_1 provide the energy for pumping of H^+ ions through the proton-conducting channel formed by the 'c' and 'a' subunits in V_0 . Unlike P-class ion pumps, V-class proton pumps are not phosphorylated and dephosphorylated during proton transport. The structurally similar F-class proton pumps, which we describe in Chapter 12, normally operate in the "reverse" direction to generate ATP rather than pump protons; their structure and mechanism of action is understood in great detail.

ABC Proteins Export a Wide Variety of Drugs and Toxins from the Cell

As noted earlier, all members of the very large and diverse ABC superfamily of transport proteins contain two transmembrane (T) domains and two cytosolic ATP-binding (A) domains (see Figure 11-9). The T domains, each built of 10 membrane-spanning α helices, form the pathway through which the transported substance (substrate) crosses the membrane (Figure 11-15a) and determine the substrate specificity of each ABC protein. The sequences of the A domains are approximately 30–40 percent homologous in all members of this superfamily, indicating a common evolutionary origin.

Discovery of the first eukaryotic ABC protein to be recognized came from studies on tumor cells and cultured cells that exhibited resistance to several drugs with unrelated chemical structures. Such cells eventually were shown to express elevated levels of a *multidrug-resistance (MDR) transport protein* originally called *MDR1* and now known as ABCB1. This protein uses the energy derived from ATP hydrolysis to *export* a large variety of drugs from the cytosol to the extracellular medium. The *Mdr1* gene is frequently amplified in multidrug-resistant cells, resulting in a large overproduction of the MDR1 protein. In contrast to bacterial ABC proteins, which are built of four discrete subunits, all four domains of mammalian ABCB1 are fused into a single 170,000-MW protein.

The substrates of mammalian ABCB1 are primarily planar, lipid-soluble molecules with one or more positive charges; they all compete with one another for transport, suggesting that they bind to the same or overlapping sites on the protein. Many drugs transported by ABCB1 diffuse from the extracellular medium across the plasma membrane,

FIGURE 11-15 The multidrug transporter ABCB1 (MDR1): structure and model of ligand export. (a) Cross-sectional view through the center of an ABCB1 protein bound to two molecules of a drug analog qz59-sss (black) reveals the central location of the ligand-binding site in relation to the phospholipid bilayer: the central ligand-binding cavity is close to the leaflet–leaflet interface of the membrane. During transport, this binding cavity is alternately exposed to the exoplasmic and the cytosolic surface of the membrane. Serines 289 and 290 affect the ligand specificity of the transporter, and are shown as red spheres to highlight their juxtaposition to the bound ligand. Surface residues are colored yellow to denote hydrophobic and blue to denote hydrophilic amino acids. (b) Three-dimensional structure of ABCB1 with its ligand-binding site facing inward toward the cytosol. In this conformation a hydrophilic ligand can bind directly from the cytosol. A more hydrophobic ligand can partition into the inner leaflet of the plasma membrane and then enter the ligand-binding site through a gap in the protein that is accessible directly to the hydrophobic core of the inner leaflet. (c) Model for the structure of ABCB1 with its ligand-binding site facing outward, based on the structures of homologous bacterial ABC proteins. When the transporter assumes this conformation the ligand can either diffuse into the exoplasmic leaflet or directly into the aqueous extracellular medium.

[After D. Gutman et al., 2009, *Trends Biochem. Sci.* **35**:36–42. Structures from S. G. Aller et al., 2009, *Science* **323**:1718–1722.]

unaided by transport proteins, into the cell cytosol, where they block various cellular functions. Two such drugs are colchicine and vinblastine, which block assembly of microtubules (Chapter 18). ATP-powered export of such drugs by MDR1 reduces their concentration in the cytosol. As a result, a much higher extracellular drug concentration is required to kill cells that express ABCB1 than those that do not. That ABCB1 is an ATP-powered small-molecule pump has been demonstrated with liposomes containing the purified protein. Different drugs enhance the ATPase activity of these liposomes in a dose-dependent manner corresponding to their ability to be transported by ABCB1.

The three-dimensional structures of ABCB1, together with those of homologous bacterial ABC transporters, revealed its mechanism of transport as well as its ability to bind and transport a wide array of hydrophilic and hydrophobic substrates (Figure 11-15). The two T domains form a binding site in the center of the membrane that alternates between an inward (Figure 11-15b) and an outward (Figure 11-15c) facing orientation. The alternation between these two conformational states of the protein is powered by ATP binding to the two A subunits and subsequent hydrolysis to ADP and P_i , but precisely how this happens is not known.

The substrate-binding cavity formed by ABCB1 is large. Some of the amino acids that line the cavity have aromatic side chains, mainly tyrosine and phenylalanine, allowing ABCB1 to bind multiple types of hydrophobic ligands. Other segments of the cavity are lined with hydrophilic residues, allowing hydrophilic or amphipathic molecules to bind. In the inward-facing conformation the binding site is open directly to the surrounding aqueous solutions, allowing hydrophilic molecules to enter the binding site directly from the cytosol. A gap in the protein is accessible directly from

the hydrophobic core of the inner leaflet of the membrane bilayer; this allows hydrophobic molecules to enter the binding site directly from the inner leaflet of the phospholipid bilayer (Figure 11-15b). After the ATP-powered change to the outward-facing conformation, molecules can exit the binding site into the exoplasmic membrane leaflet or directly into the extracellular medium (Figure 11-15c).

About 50 different mammalian ABC transport proteins are now recognized (Table 11-3). Several are expressed in abundance in the liver, intestines, and kidney—sites where natural toxic and waste products are removed from the body. Substrates for these ABC proteins include sugars, amino acids, cholesterol, bile acids, phospholipids, peptides, proteins, toxins, and foreign substances. The normal function of ABCB1 most likely is to transport various natural and metabolic toxins into the bile or intestinal lumen for excretion or into the urine being formed in the kidney. During the course of its evolution, ABCB1 appears to have acquired the ability to transport drugs whose structures are similar to those of these endogenous toxins. Tumors derived from MDR-expressing cell types, such as hepatomas (liver cancers), frequently are resistant to virtually all chemotherapeutic agents and are thus difficult to treat, presumably because the tumors exhibit increased expression of ABCB1 or a related ABC protein.

Certain ABC Proteins “Flip” Phospholipids and Other Lipid-Soluble Substrates from One Membrane Leaflet to the Other

As shown in Figure 11-15b and c, ABCB1 can move, or “flip,” a hydrophobic or amphipathic substrate molecule from the inner leaflet of the membrane to the outer leaflet. This is an otherwise energetically unfavorable reaction powered by the

TABLE 11-3 Selected Human ABC Proteins

Protein	Tissue Expression	Function	Disease Caused by Defective Protein
ABCB1 (MDR1)	Adrenal, kidney, brain	Exports lipophilic drugs	
ABCB4 (MDR2)	Liver	Exports phosphatidylcholine into bile	
ABCB11	Liver	Exports bile salts into bile	
CFTR	Exocrine tissue	Transports Cl ions	Cystic fibrosis
ABCD1	Ubiquitous in peroxisomal membrane	Influences activity of peroxisomal enzyme that oxidizes very long chain fatty acids	Adrenoleukodystrophy (ADL)
ABCG5/8	Liver, intestine	Exports cholesterol and other sterols	β -Sitosterolemia
ABCA1	Ubiquitous	Exports cholesterol and phospholipid for uptake into high-density lipoprotein (HDL)	Tangier's disease

coupled ATPase activity of the protein. Support for this so-called *flippase* model of transport by ABCB1 comes from experiments on ABCB4 (originally called MDR2), a protein homologous to ABCB1 that is present in the region of the liver-cell plasma membrane that faces the bile canaliculi. ABCB4 moves phosphatidylcholine from the cytosolic to the exoplasmic leaflet of the plasma membrane for subsequent release into the bile in combination with cholesterol and bile acids, which themselves are transported by other ABC family members. Several other ABC superfamily members participate

in the cellular export of various lipids, presumably by mechanisms similar to that of ABCB1 (see Table 11-3).

ABCB4 was first suspected of having phospholipid flippase activity because mice with homozygous loss-of-function mutations in the *ABCB4* gene exhibited defects in the secretion of phosphatidylcholine into bile. To determine directly if ABCB4 was in fact a flippase, researchers performed experiments on a homogeneous population of purified vesicles isolated from special mutant yeast cells with ABCB4 in the membrane and with the cytosolic face directed outward (Figure 11-16). After

EXPERIMENTAL FIGURE 11-16 In vitro fluorescence-quenching assay can detect phospholipid flippase activity of ABCB4. A homogeneous population of secretory vesicles containing ABCB4 protein was obtained by introducing the cDNA encoding mammalian ABCB4 into a temperature-sensitive yeast *sec* mutant such that ABCB4 was localized to intracellular endoplasmic reticulum vesicles in its normal orientation and with the cytosolic face of the vesicles facing outward (see Figure 14-4). Step 1: Synthetic phospholipids containing a fluorescently modified head group (blue) were incorporated primarily into the outer, cytosolic leaflets of the purified vesicles. Step 2: If ABCB4 acted as a flippase, then on addition of ATP to the outside of the vesicles, a small fraction of the outward-facing labeled phospholipids would be flipped to the inside leaflet. Step 3: Flipping was detected by adding a membrane-impermeable quenching compound called dithionite to the medium surrounding the

vesicles. Dithionite reacts with the fluorescent head group, destroying its ability to fluoresce (gray). In the presence of the quencher, only labeled phospholipid in the protected environment on the inner leaflet will fluoresce. Subsequent to the addition of the quenching agent, the total fluorescence decreases with time until it plateaus at the point at which all external fluorescence is quenched and only the internal phospholipid fluorescence can be detected. The observation of greater fluorescence (less quenching) in the presence of ATP than in its absence indicates that ABCB4 has flipped some of the labeled phospholipid to the inside. Not shown here are "control" vesicles isolated from cells that did not express ABCB4 and that exhibited no flippase activity. Step 4: Addition of detergent to the vesicles generates micelles and makes all fluorescent lipids accessible to the quenching agent, lowering the fluorescence to baseline values. [Adapted from S. Ruetz and P. Gros, 1994, *Cell* 77:1071.]

purifying these vesicles, investigators labeled them *in vitro* with a fluorescent phosphatidylcholine derivative. The fluorescence-quenching assay outlined in Figure 11-16 was used to demonstrate that the vesicles containing ABCB4 exhibited an ATP-dependent flippase activity.

The ABC Cystic Fibrosis Transmembrane Regulator (CFTR) Is a Chloride Channel, Not a Pump

Several human genetic diseases are associated with defective ABC proteins (see Table 11-3). The best studied and most widespread is cystic fibrosis (CF), caused by a mutation in the gene encoding the *cystic fibrosis transmembrane regulator* (CFTR, also called ABCC7). Like other ABC proteins, CFTR has two transmembrane T domains and two cytosolic A, or ATP-binding, domains. CFTR contains an additional R (regulatory) domain on the cytosolic face; R links the two homologous halves of the protein, creating an overall domain organization of T1–A1–R–T2–A2. But CFTR is a Cl^- channel protein, not an ion pump. It is expressed in the apical plasma membranes of epithelial cells in the lung, sweat glands, pancreas, and other tissues. For instance, CFTR protein is important for reuptake, into the cells of sweat glands, of Cl^- lost by sweating; babies with cystic fibrosis, if licked, often taste “salty” because this reuptake is inhibited.

The Cl^- channel of CFTR is normally shut. Channel opening is activated by phosphorylation of the R domain by a protein kinase (PKA, discussed in Chapter 15) that in turn is activated by an increase in cyclic AMP (cAMP), a small intracellular signaling molecule. Opening of the channel also requires sequential binding of two ATP molecules to the two A domains (Figure 11-17).

■ About two-thirds of all CF disease cases can be attributed to a single mutation in CFTR: deletion of Phe 508 in the ATP-binding A1 domain. At body temperature, the

mutant protein fails to fold properly and to move to the cell surface where it normally functions. Interestingly, if cells expressing the mutant protein are incubated at room temperature, the protein accumulates normally on the plasma membrane, where it functions nearly as well as the wild-type CFTR channel. Much effort is now being directed toward identifying small molecules that might allow the mutant protein in CF patients to traffic normally to the cell surface and thus reverse the effects of the disease. ■

KEY CONCEPTS of Section 11.3

ATP-Powered Pumps and the Intracellular Ionic Environment

- Four classes of transmembrane proteins couple the energy-releasing hydrolysis of ATP with the energy-requiring transport of substances against their concentration gradients: P-, V-, and F-class pumps and ABC proteins (see Figure 11-9).
- The combined action of P-class Na^+/K^+ ATPases in the plasma membrane and homologous Ca^{2+} ATPases in the plasma membrane or sarcoplasmic reticulum creates the usual ionic milieu of animal cells: high K^+ , low Ca^{2+} , and low Na^+ in the cytosol; low K^+ , high Ca^{2+} , and high Na^+ in the extracellular fluid.
- In P-class pumps, phosphorylation of the α (catalytic) subunit and changes in conformational states are essential for coupling ATP hydrolysis to transport of H^+ , Na^+ , K^+ , or Ca^{2+} ions (see Figures 11-10 through 11-13).
- V- and F-class ATPases, which transport protons exclusively, are large, multisubunit complexes with a proton-conducting channel in the transmembrane domain and ATP-binding sites in the cytosolic domain.
- V-class H^+ pumps in animal lysosomal and endosomal membranes and plant vacuolar membranes are responsible

FIGURE 11-17 Structure and function of the cystic fibrosis transmembrane regulator (CFTR). Structural interpretation of the ATP-dependent gating cycle of phosphorylated CFTR channels.

The regulatory (R) domain (not depicted) must be phosphorylated before ATP is able to support channel opening. One ATP (yellow circle) becomes tightly bound to the A1 domain (green). Binding of the second ATP to the A2 domain (blue) is followed by formation of a tight intramolecular A1–A2 heterodimer and slow channel opening. The relatively stable open state becomes destabilized by hydrolysis of the ATP bound at A2 to ADP (red crescent) and P_i . The ensuing disruption of the tight A1–A2 dimer interface leads to channel closure. T = transmembrane domain; A = cytosolic ATP-binding domain. [After D. C. Gadsby et al., 2006, *Nature* **440**:477 and S. G. Aller, 2009, *Science* **323**:1718.]

for maintaining a lower pH inside the organelles than in the surrounding cytosol (see Figure 11-14).

- All members of the large and diverse ABC superfamily of transport proteins contain four core domains: two transmembrane domains, which form a pathway for solute movement and determine substrate specificity, and two cytosolic ATP-binding domains (see Figure 11-15).
- The ABC superfamily includes bacterial amino acid and sugar permeases and about 50 mammalian proteins (e.g., ABCB1, ABCA1) that transport a wide array of substrates, including toxins, drugs, phospholipids, peptides, and proteins, into or out of the cell.
- The two T domains of the multidrug transporter ABCB1 form a ligand-binding site in the middle of the plane of the membrane; ligands can bind directly from the cytosol or from the inner membrane leaflet through a gap in the protein.
- Biochemical experiments directly demonstrate that ABCB4 (MDR2) possesses phospholipid flippase activity (see Figure 11-16).
- CFTR, an ABC protein, is a Cl^- channel protein, not an ion pump. Channel opening is triggered by protein phosphorylation and by binding of ATP to the two A domains (Figure 11-17).

11.4 Nongated Ion Channels and the Resting Membrane Potential

In addition to ATP-powered ion pumps, which transport ions *against* their concentration gradients, the plasma membrane contains channel proteins that allow the principal cellular ions (Na^+ , K^+ , Ca^{2+} , and Cl^-) to move through them at different rates *down* their concentration gradients. Ion concentration gradients generated by pumps and selective movements of ions through channels constitute the principal mechanism by which a difference in voltage, or electric potential, is generated across the plasma membrane. In other words, ATP-powered ion pumps generate differences in ion concentrations across the plasma membrane, and ion channels utilize these concentration gradients to generate a tightly controlled electric potential across the membrane (see Figure 11-3).

In all cells the magnitude of this electric potential generally is ~ 70 millivolts (mV), with the *inside* cytosolic face of the cell membrane always *negative* with respect to the *exoplasmic* face. This value does not seem like much until we consider that the thickness of the plasma membrane is only ~ 3.5 nm. Thus the voltage gradient across the plasma membrane is 0.07 V per 3.5×10^{-7} cm, or 200,000 volts per centimeter! (To appreciate what this means, consider that high-voltage transmission lines for electricity utilize gradients of about 200,000 volts per kilometer, 10^5 -fold less!)

The ionic gradients and electric potential across the plasma membrane play crucial roles in many biological

processes. As noted previously, a rise in the cytosolic Ca^{2+} concentration is an important regulatory signal, initiating contraction in muscle cells and triggering in many cells secretion of proteins, such as digestive enzymes from pancreatic cells. In many animal cells, the combined force of the Na^+ concentration gradient and membrane electric potential drives the uptake of amino acids and other molecules against their concentration gradients by symport and antiport proteins (see Figure 11-3 and Section 11.5). Furthermore, the electrical signaling by nerve cells depends on the opening and closing of ion channels in response to changes in the membrane electric potential (Chapter 22).

Here, we discuss the origin of the membrane electric potential in resting non-neuronal cells, often called the cell's "resting potential"; how ion channels mediate the selective movement of ions across a membrane; and useful experimental techniques for characterizing the functional properties of channel proteins.

Selective Movement of Ions Creates a Transmembrane Electric Gradient

To help explain how an electric potential across the plasma membrane can arise, we first consider a set of simplified experimental systems in which a membrane separates a 150 mM NaCl/15 mM KCl solution (similar to the extracellular medium surrounding metazoan cells) on the right from a 15 mM NaCl/150 mM KCl solution (similar to that of the cytosol) on the left (Figure 11-18a). A potentiometer (voltmeter) is connected to both solutions to measure any difference in electric potential across the membrane. If the membrane is impermeable to all ions, no ions will flow across it. Initially both solutions contain an equal number of positive and negative ions. Furthermore, there will be no difference in voltage, or electric potential gradient, across the membrane, as shown in Figure 11-18a.

Now suppose that the membrane contains Na^+ -channel proteins that accommodate Na^+ ions but exclude K^+ and Cl^- ions (Figure 11-18b). Na^+ ions then tend to move down their concentration gradient from the right side to the left, leaving an excess of negative Cl^- ions compared with Na^+ ions on the right side and generating an excess of positive Na^+ ions compared with Cl^- ions on the left side. The excess Na^+ on the left and Cl^- on the right remain near the respective surfaces of the membrane because the excess positive charges on one side of the membrane are attracted to the excess negative charges on the other side. The resulting separation of charge across the membrane constitutes an electric potential, or voltage, with the left (cytosolic) side of the membrane having excess positive charge with respect to the right.

As more and more Na^+ ions move through channels across the membrane, the magnitude of this charge difference (i.e., voltage) increases. However, continued right-to-left movement of the Na^+ ions eventually is inhibited by the mutual repulsion between the excess positive (Na^+) charges accumulated on the left side of the membrane and by the attraction of Na^+ ions to the excess negative charges built up

(a) Membrane impermeable to Na^+ , K^+ , and Cl^-

(b) Membrane permeable only to Na^+

(c) Membrane permeable only to K^+

EXPERIMENTAL FIGURE 11-18 Generation of a transmembrane electric potential (voltage) depends on the selective movement of ions across a semipermeable membrane. In this experimental system, a membrane separates a 15 mM NaCl/150 mM KCl solution (left) from a 150 mM NaCl/15 mM KCl solution (right); these ion concentrations are similar to those in cytosol and blood, respectively. If the membrane separating the two solutions is impermeable to all ions (a), no ions can move across the membrane and no difference in electric potential is registered on the potentiometer connecting the two solutions. If the membrane is selectively permeable only to Na^+ (b) or to K^+ (c), then diffusion of ions through their respective channels leads to a separation of charge across the membrane. At equilibrium, the membrane potential caused by the charge separation becomes equal to the Nernst potential E_{Na} or E_{K} registered on the potentiometer. See the text for further explanation.

on the right side. The system soon reaches an equilibrium point at which the two opposing factors that determine the movement of Na^+ ions—the membrane electric potential and the ion concentration gradient—balance each other out. At equilibrium, no net movement of Na^+ ions occurs across the membrane. Thus this membrane, like all biological membranes, acts as a *capacitor*—a device consisting of a thin sheet of nonconducting material (the hydrophobic interior) surrounded on both sides by electrically conducting material (the polar phospholipid head groups and the ions in the surrounding aqueous solution) that can store positive charges on one side and negative charges on the other.

If a membrane is permeable only to Na^+ ions, then at equilibrium the measured electric potential across the membrane equals the sodium equilibrium potential in volts, E_{Na} . The magnitude of E_{Na} is given by the *Nernst equation*, which is derived from basic principles of physical chemistry:

$$E_{\text{Na}} = \frac{RT}{ZF} \ln \frac{[\text{Na}_{\text{right}}]}{[\text{Na}_{\text{left}}]} \quad (11-2)$$

where R (the gas constant) = 1.987 cal/(degree · mol), or 8.28 joules/(degree · mol); T (the absolute temperature in degrees Kelvin) = 293 °K at 20 °C; Z (the charge, also called the valency) here equal to +1; F (the Faraday constant) = 23,062 cal/(mol · V), or 96,000 coulombs/(mol · V); and $[\text{Na}_{\text{left}}]$ and $[\text{Na}_{\text{right}}]$ are the Na^+ concentrations on the left and right sides, respectively, at equilibrium. By convention the potential is expressed as the *cytosolic* face of the membrane relative to the *exoplasmic* face, and the equation is written with the concentration of ion in the extracellular solution (here the right side of the membrane) placed in the numerator and that of the cytosol in the denominator.

At 20 °C, Equation 11-2 reduces to

$$E_{\text{Na}} = 0.059 \log_{10} \frac{[\text{Na}_{\text{right}}]}{[\text{Na}_{\text{left}}]} \quad (11-3)$$

If $[\text{Na}_{\text{right}}]/[\text{Na}_{\text{left}}] = 10$, a tenfold ratio of concentrations as in Figure 11-18b, then $E_{\text{Na}} = +0.059 \text{ V}$ (or +59 mV), with

the left, cytosolic side positive with respect to the exoplasmic right side.

If the membrane is permeable only to K^+ ions and not to Na^+ or Cl^- ions, then a similar equation describes the potassium equilibrium potential E_K :

$$E_K = 0.059 \log_{10} \frac{[K]_{\text{right}}}{[K]_{\text{left}}} \quad (11-4)$$

The *magnitude* of the membrane electric potential is the same (59 mV, for a tenfold difference in ion concentrations), except that the left, cytosolic side is now *negative* with respect to the right (Figure 11-18c), opposite to the polarity obtained across a membrane selectively permeable to Na^+ ions.

The Resting Membrane Potential in Animal Cells Depends Largely on the Outward Flow of K^+ Ions Through Open K^+ Channels

The plasma membranes of animal cells contain many open K^+ channels but few open Na^+ , Cl^- , or Ca^{2+} channels. As a result, the major ionic movement across the plasma membrane is that of K^+ from the *inside outward*, powered by the K^+ concentration gradient, leaving an excess of *negative* charge on the cytosolic face of the plasma membrane and creating an excess of *positive* charge on the exoplasmic face, similar to the experimental system shown in Figure 11-18c. This outward flow of K^+ ions through these channels, called **resting K^+ channels**, is the major determinant of the inside-negative membrane potential. Like all channels, these alternate between an open and a closed state (Figure 11-2), but since their opening and closing are not affected by the membrane potential or by small signaling molecules, these channels are called *nongated*. The various gated channels in nerve cells (Chapter 22) open only in response to specific ligands or to changes in membrane potential.

Quantitatively, the usual resting membrane potential of -70 mV is close to the potassium equilibrium potential, calculated from the Nernst equation and the K^+ concentrations in cells and surrounding media depicted in Table 11-2. Usually the potential is lower (less negative) than that calculated from the Nernst equation because of the presence of a few open Na^+ channels. These open Na^+ channels allow the net *inward* flow of Na^+ ions, making the cytosolic face of the plasma membrane more positive, that is, less negative, than predicted by the Nernst equation for K^+ . The K^+ concentration gradient that drives the flow of ions through resting K^+ channels is generated by the Na^+/K^+ ATPase described previously (see Figures 11-3 and 11-13). In the absence of this pump, or when it is inhibited, the K^+ concentration gradient cannot be maintained, the magnitude of the membrane potential falls to zero, and the cell eventually dies.

Although resting K^+ channels play the dominant role in generating the electric potential across the plasma membrane of animal cells, this is not the case in bacterial, plant, and fungal cells. The inside-negative membrane potential in plant and fungal cells is generated by transport of positively charged protons (H^+) out of the cell by ATP-powered pro-

EXPERIMENTAL FIGURE 11-19 The electric potential across the plasma membrane of living cells can be measured. A microelectrode, constructed by filling a glass tube of extremely small diameter with a conducting fluid such as a KCl solution, is inserted into a cell in such a way that the surface membrane seals itself around the tip of the electrode. A reference electrode is placed in the bathing medium. A potentiometer connecting the two electrodes registers the potential, in this case -60 mV with the cytosolic face *negative* with respect to the exoplasmic face of the membrane. A potential difference is registered only when the microelectrode is inserted into the cell; no potential is registered if the microelectrode is in the bathing fluid.

ton pumps, a process similar to what occurs in lysosomal membranes lacking Cl^- channels (see Figure 11-14a): each H^+ pumped out of the cell leaves behind a Cl^- ion, generating an electric potential gradient (cytosolic face negative) across the membrane. In aerobic bacterial cells the inside negative potential is generated by outward pumping of protons during electron transport, a process similar to proton pumping in mitochondrial inner membranes that will be discussed in detail in Chapter 12 (see Figure 12-16).

The potential across the plasma membrane of large cells can be measured with a microelectrode inserted inside the cell and a reference electrode placed in the extracellular fluid. The two are connected to a potentiometer capable of measuring small potential differences (Figure 11-19). The potential across the surface membrane of most animal cells generally does not vary with time. In contrast, neurons and muscle cells—the principal types of electrically active cells—undergo controlled changes in their membrane potential, as we discuss in Chapter 22.

Ion Channels Are Selective for Certain Ions by Virtue of a Molecular “Selectivity Filter”

All ion channels exhibit specificity for particular ions: K^+ channels allow K^+ but not closely related Na^+ ions to enter, whereas Na^+ channels admit Na^+ but not K^+ . Determination of the three-dimensional structure of a bacterial K^+ channel first revealed how this exquisite ion selectivity is achieved. Comparisons of the sequences and structures of other K^+ channels from organisms as diverse as bacteria, fungi, and

(a) Single subunit

(b) Tetrameric channel

FIGURE 11-20 Structure of a resting K^+ channel from the bacterium *Streptomyces lividans*. All K^+ channel proteins are tetramers comprising four identical subunits, each containing two conserved membrane-spanning α helices, called by convention S5 and S6, and a shorter P, or pore segment. (a) One of the subunits, viewed from the side, with key structural features indicated. (b) The complete tetrameric channel viewed from the side (left) and the top, or extracellular end (right). The P segments (pink) are located near the exoplasmic surface and connect the S5 and S6 α helices (yellow and silver); they

consist of a nonhelical "turret," which lines the upper part of the pore; a short α helix; and an extended loop that protrudes into the narrowest part of the pore and forms the ion-selectivity filter. This filter allows K^+ (purple spheres) but not other ions to pass. Below the filter is the central cavity or vestibule lined by the inner, or S6, α helices. The subunits in gated K^+ channels, which open and close in response to specific stimuli, contain additional transmembrane helices not shown here; these are discussed in Chapter 22. [See Y. Zhou et al., 2001, *Nature* 414:43.]

humans established that all share a common structure and probably evolved from a single type of channel protein.

Like all other K^+ channels, bacterial K^+ channels are built of four identical transmembrane subunits symmetrically arranged around a central pore (Figure 11-20). Each subunit contains two membrane-spanning α helices (S5 and S6) and a short P (pore) segment that partly penetrates the membrane bilayer from the exoplasmic surface. In the tetrameric K^+ channel, the eight transmembrane α helices (two from each subunit) form an inverted cone, generating a water-filled cavity called the *vestibule* in the central portion of the channel that extends halfway through the membrane toward the cytosolic side. Four extended loops that are part of the four P segments form the actual *ion-selectivity filter* in the narrow part of the pore near the exoplasmic surface, above the vestibule.

Several related pieces of evidence support the role of P segments in ion selection. First, the amino acid sequence of the P segment is highly homologous in all known K^+ channels and is different from that in other ion channels. Second, mutation of certain amino acids in this segment alters the ability of a K^+ channel to distinguish Na^+ from K^+ . Finally, replacing the P segment of a bacterial K^+ channel with the homologous segment from a mammalian K^+ channel yields a chimeric protein that exhibits normal selectivity for K^+ over other ions. Thus all K^+ channels are thought to use the same mechanism to distinguish K^+ from other ions.

Na^+ ions are smaller than K^+ ions. How, then, can a channel protein exclude smaller Na^+ ions, yet allow passage of larger K^+ ? The ability of the ion-selectivity filter in K^+ channels

to select K^+ over Na^+ is due mainly to backbone carbonyl oxygens on residues located in a Gly-Tyr-Gly sequence that is found in an analogous position in the P segment in every known K^+ channel. As a K^+ ion enters the narrow selectivity filter—the space between the P segment filter sequences contributed by the four adjacent subunits—it loses its eight waters of hydration but becomes bound in the same geometry to eight backbone carbonyl oxygens, two from the extended loop in each of the four P segments lining the channel (Figure 11-21a, bottom left). Thus little energy is required to strip off the eight waters of hydration of a K^+ ion, and as a result, a relatively low activation energy is required for passage of K^+ ions into the channel from an aqueous solution. A dehydrated Na^+ ion is too small to bind to all eight carbonyl oxygens that line the selectivity filter with the same geometry as a Na^+ ion surrounded by its normal eight water molecules in aqueous solution. As a result, Na^+ ions would "prefer" to remain in water rather than enter the selectivity filter, and thus the change in free energy for entry of Na^+ ions into the channel is relatively high (Figure 11-21a, right). This difference in free energies favors passage of K^+ ions through the channel over Na^+ by a factor of 1000. Like Na^+ , the dehydrated Ca^{2+} ion is smaller than the dehydrated K^+ ion and cannot interact properly with the oxygen atoms in the selectivity filter. Also, because a Ca^{2+} ion has two positive charges and binds water oxygens more tightly than does a single positive Na^+ or K^+ ion, more energy is required to strip the waters of hydration from Ca^{2+} than from K^+ or Na^+ .

Recent x-ray crystallographic studies reveal that both when open and when closed, the channel contains K^+ ions

(b) K^+ ions in the pore of a K^+ channel (side view)

(c) Ion movement through selectivity filter

FIGURE 11-21 Mechanism of ion selectivity and transport in resting K^+ channels. (a) Schematic diagrams of K^+ and Na^+ ions hydrated in solution and in the pore of a K^+ channel.

As K^+ ions pass through the selectivity filter, they lose their bound water molecules and become coordinated instead to eight backbone carbonyl oxygens, four of which are shown, that are part of the conserved amino acids in the channel-lining selectivity filter loop of each P segment. The smaller Na^+ ions with their tighter shell of water molecules cannot perfectly coordinate with the channel oxygen atoms and therefore pass through the channel only rarely. (b) High-resolution electron density map obtained from x-ray crystallography showing K^+ ions (purple spheres) passing through the selectivity filter. Only two of the diagonally opposed channel subunits are shown. Within the selectivity filter each unhydrated K^+ ion interacts with eight carbonyl oxygen atoms (red sticks) lining the channel, two from each of the four subunits, as if to mimic the eight waters of hydration. (c) Interpretation of the electron density map showing the two alternating states by which K^+ ions move through the channel. In state 1, numbered top-to-bottom from the exoplasmic side of the channel inward, one sees a hydrated K^+ ion with its eight bound water molecules, K^+ ions at positions 1 and 3 within the selectivity filter, and a fully hydrated K^+ ion within the vestibule. During K^+ movement each ion in state 1 moves one step inward, forming state 2. Thus in state 2 the K^+ ion on the exoplasmic side of the channel has lost four of its eight waters, the ion at position 1 in state 1 has moved to position 2, and the ion at position 3 in state 1 has moved to position 4. In going from state 2 to state 1, the K^+ at position 4 moves into the vestibule and picks up eight water molecules, while another hydrated K^+ ion moves into the channel opening and the other K^+ ions move down one step. Note that K^+ ions are shown here moving from the exoplasmic side of the channel to the cytosolic side because that is the normal direction of movement in bacteria. In animal cells the direction of K^+ movement is typically the reverse—from inside to outside. [Part (a) adapted from C. Armstrong, 1998, *Science* **280**:56. Parts (b) and (c) adapted from Y. Zhou et al., 2001, *Nature* **414**:43.]

within the selectivity filter; without these ions the channel probably would collapse. The K^+ ions are thought to be present either at positions 1 and 3 or at 2 and 4, each surrounded by eight carbonyl oxygen atoms (Figure 11-21b and c). Several K^+ ions move simultaneously through the channel such that when the ion on the exoplasmic face that has been partially stripped of its water of hydration moves into position 1, the ion at position 2 jumps to position 3 and the one at position 4 exits the channel (Figure 11-21c).

Although the amino acid sequences of the P segments in Na^+ and K^+ channels differ somewhat, they are similar enough to suggest that the general structure of the ion-selectivity filters are comparable in both types of channels. Presumably the diameter of the filter in Na^+ channels is small enough that it permits dehydrated Na^+ ions to bind to the backbone carbonyl oxygens but excludes the larger K^+ ions from entering, but the first three-dimensional structure of a sodium channel was determined only in late 2011 and the mechanism of ion selectivity is only now being determined.

Patch Clamps Permit Measurement of Ion Movements Through Single Channels

Once it was realized that in most cells there are only one or a few ion channels per square micrometer of plasma membrane,

EXPERIMENTAL FIGURE 11-22 Current flow through individual ion channels can be measured by patch-clamping.

(a) Basic experimental arrangement for measuring current flow through individual ion channels in the plasma membrane of a living cell. The patch electrode, filled with a current-conducting saline solution, is applied, with a slight suction, to the plasma membrane. The 0.5- μm -diameter tip covers a region that contains only one or a few ion channels. The second electrode is inserted through the membrane into the cytosol. A recording device measures current flow only through the channels in the patch of plasma membrane. (b) Photomicrograph of the cell body of a cultured neuron and the tip of a patch pipette touching the cell membrane. (c) Different patch-clamping configurations. Isolated, detached patches are the best configurations for studying the effects on channels of different ion concentrations and solutes such as extracellular hormones and intracellular second messengers (e.g., cAMP). An inside-out patch, in which an on-cell patch is formed and then the cell pulled away, is used in the experiment in Figure 11-23. [Part (b) from B. Sakmann, 1992, *Neuron* 8:613 (Nobel lecture); also published in E. Neher and B. Sakmann, 1992, *Sci. Am.* 266(3):44. Part (c) adapted from B. Hille, 1992, *Ion Channels of Excitable Membranes*, 2d ed., Sinauer Associates, p. 89.]

The inward or outward movement of ions across a patch of membrane is quantified from the amount of electric current needed to maintain the membrane potential at a particular “clamped” value (Figure 11-22a and b). To preserve electro-neutrality and to keep the membrane potential constant even though ions are moving through channels in the membrane patch, the entry of each positive ion (e.g., a Na^+ ion) into the cell through a channel in the patch of membrane is balanced by the addition of an electron into the cytosol through a microelectrode inserted into the cytosol; an electronic device measures the numbers of electrons (current) required to counterbalance the inflow of ions through the membrane channels. Conversely, the exit of each positive ion from the cell (e.g., a K^+ ion) is balanced by the withdrawal of an electron from the cytosol. The patch-clamping technique can be employed on whole cells or isolated membrane patches to measure the effects of different substances and ion concentrations on ion flow (Figure 11-22c).

The patch-clamp tracings in Figure 11-23 illustrate the use of this technique to study the properties of voltage-gated Na^+ channels in the plasma membrane of muscle cells. As we discuss in Chapter 22, these channels normally are closed in resting muscle cells and open following nervous stimulation. Patches of muscle membrane, each containing on average one Na^+ channel, were clamped at a predetermined voltage that, in this study, was slightly less than the resting membrane potential. Under these circumstances, transient pulses of positive charges (Na^+ ions) cross the membrane from the exoplasmic to the cytosolic face as individual Na^+ channels open and then close. Each channel is either fully open or completely closed. From such tracings, it is possible to determine the time that a channel is open and the ion flux through it. For the channels measured in Figure 11-23, the flux is about 10 million Na^+ ions per channel per second, a typical value for ion channels. Replacement of the NaCl within the

it became possible to record ion movements through single ion channels, and to measure the rates at which these channels open and close and conduct specific ions, using a technique known as **patch clamping** or voltage clamping. As illustrated in Figure 11-22, a tiny pipette is tightly applied to the surface of a cell; the segment of the plasma membrane within the tip will contain only one or a few ion channels. An electrical recording device detects ion flow, measured as electric current, through the channels; this usually occurs in small bursts when the channel is open. An electrical device “clamps” or locks the electric potential across the membrane at a predetermined value (hence the term patch clamping).

EXPERIMENTAL FIGURE 11-23 Ion flux through individual Na^+ channels can be calculated from patch clamp tracings. Two inside-out patches of muscle plasma membrane were clamped at a potential of slightly less than that of the resting membrane potential. The patch electrode contained NaCl. The transient pulses of electric current in picoamperes (pA), recorded as large downward deviations (blue arrows), indicate the opening of a Na^+ channel and movement of positive charges (Na^+ ions) inward across the membrane. The smaller deviations in current represent background noise. The average current through an open channel is 1.6 pA, or 1.6×10^{-12} amperes. Since 1 ampere = 1 coulomb (C) of charge per second, this current is equivalent to the movement of about 9900 Na^+ ions per channel per millisecond: $(1.6 \times 10^{-12} \text{ C/s}) / (10^{-3} \text{ s/ms}) (6 \times 10^{23} \text{ molecules/mol}) + 96,500 \text{ C/mol}$. [See F. J. Sigworth and E. Neher, 1980, *Nature* 287:447.]

patch pipette (corresponding to the outside of the cell) with KCl or choline chloride abolishes current through the channels, confirming that they conduct only Na^+ ions, not K^+ or other ions.

Novel Ion Channels Can Be Characterized by a Combination of Oocyte Expression and Patch Clamping

Cloning of human-disease-causing genes and sequencing of the human genome have identified many genes encoding putative channel proteins, including 67 putative K^+ channel proteins. One way of characterizing the function of these proteins is to transcribe a cloned cDNA in a cell-free system to produce the corresponding mRNA. Injecting this mRNA into frog oocytes and taking patch clamp measurements of the newly synthesized channel protein can often reveal its function (Figure 11-24). This experimental approach is especially useful because frog oocytes normally do not express any channel proteins on their surface membrane, so only the channel under study is present in the membrane. In addition, because of the large size of frog oocytes, patch-clamping studies are technically easier to perform on them than on smaller cells.

KEY CONCEPTS of Section 11.4

Nongated Ion Channels and the Resting Membrane Potential

- An inside-negative electric potential (voltage) of about -70 mV exists across the plasma membrane of all cells.
- The resting membrane potential in animal cells is the result of the combined action of the ATP-powered Na^+/K^+ pump,

EXPERIMENTAL FIGURE 11-24 Oocyte expression assay is useful in comparing the function of normal and mutant forms of a channel protein. A follicular frog oocyte is first treated with collagenase to remove the surrounding follicle cells, leaving a denuded oocyte, which is microinjected with mRNA encoding the channel protein under study. [Adapted from T. P. Smith, 1988, *Trends Neurosci.* 11:250.]

which establishes Na^+ and K^+ concentration gradients across the membrane, and resting K^+ channels which permit selective movement only of K^+ ions back down their concentration gradient to the external medium (see Figure 11-3).

- Unlike the more common gated ion channels, which open only in response to various signals, these nongated K^+ channels are usually open.
- The electric potential generated by the selective flow of ions across a membrane can be calculated using the Nernst equation (see Equation 11-2).
- In plants and fungi, the membrane potential is maintained by the ATP-driven pumping of protons from the cytosol to the exterior of the cell.
- K^+ channels are assembled from four identical subunits, each of which has at least two conserved membrane-spanning α helices and a nonhelical P segment that lines the ion pore and forms the selectivity filter (see Figure 11-20).
- The ion specificity of K^+ channel proteins is due mainly to coordination of the selected ion with eight carbonyl oxygen atoms of specific amino acids in the P segments, which lowers the activation energy for passage of the selected K^+ compared with Na^+ or other ions (see Figure 11-21).
- Patch-clamping techniques, which permit measurement of ion movements through single channels, are used to determine

the ion conductivity of a channel and the effect of various signals on its activity (see Figure 11-22).

- Recombinant DNA techniques and patch clamping allow the expression and functional characterization of channel proteins in frog oocytes (see Figure 11-24).

11.5 Cotransport by Symporters and Antiporters

In previous sections we saw how ATP-powered pumps generate ion concentration gradients across cell membranes and how K^+ channel proteins use the K^+ concentration gradient to establish an electric potential across the plasma membrane. In this section we see how cotransporters use the energy stored in the electric potential and concentration gradients of Na^+ or H^+ ions to power the uphill movement of another substance, which may be a small organic molecule such as glucose or an amino acid or a different ion. An important feature of such **cotransport** is that neither substance can move alone; movement of both substances together is obligatory, or *coupled*.

Cotransporters share common features with uniporters such as the GLUT proteins. The two types of transporters exhibit certain structural similarities, operate at equivalent rates, and undergo cyclical conformational changes during transport of their substrates. They differ in that uniporters can only accelerate thermodynamically favorable transport down a concentration gradient, whereas cotransporters can harness the energy released when one substance moves down its concentration gradient to drive the movement of another substance against its concentration gradient.

When the transported molecule and cotransported ion move in the same direction, the process is called **symport**; when they move in opposite directions, the process is called **antiport** (see Figure 11-2). Some cotransporters transport only positive ions (cations), while others transport only negative ions (anions). Yet other cotransporters mediate movement of both cations and anions together. Cotransporters are present in all organisms, including bacteria, plants, and animals, and in this section we describe the operation and function of several physiologically important symporters and antiporters.

Na^+ Entry into Mammalian Cells Is Thermodynamically Favored

Mammalian cells express many types of Na^+ -coupled symporters. The human genome encodes literally hundreds of different types of transport proteins that use the energy stored across the plasma membrane in the Na^+ concentration gradient and in the inside-negative electric potential across the membrane to transport a wide variety of molecules into cells against their concentration gradients. To see why such transporters allow cells to accumulate substrates against a considerable concentration gradient we first need

to calculate the change in free energy (ΔG) that occurs during Na^+ entry. As mentioned earlier, two forces govern the movement of ions across selectively permeable membranes: the voltage and the ion concentration gradient across the membrane. The sum of these forces constitutes the electrochemical gradient. To calculate the free-energy change, ΔG , corresponding to the transport of any ion across a membrane, we need to consider the independent contributions from each of the forces to the electrochemical gradient.

For example, when Na^+ moves from outside to inside the cell, the free-energy change generated from the Na^+ concentration gradient is given by

$$\Delta G_c = RT \ln \frac{[Na]_{in}}{[Na]_{out}} \quad (11-5)$$

At the concentrations of Na_{in} and Na_{out} shown in Figure 11-25, which are typical for many mammalian cells, ΔG_c , the change in free energy due to the concentration gradient, is -1.45 kcal for transport of 1 mol of Na^+ ions from outside to inside a cell, assuming there is no membrane electric potential. Note the free energy is negative, indicating spontaneous movement of Na^+ into the cell down its concentration gradient.

The free-energy change generated from the membrane electric potential is given by

$$\Delta G_m = FE \quad (11-6)$$

where F is the Faraday constant [$= 23,062 \text{ cal}/(\text{mol} \cdot \text{V})$]; and E is the membrane electric potential. If $E = -70 \text{ mV}$, then ΔG_m , the free-energy change due to the membrane potential, is -1.61 kcal for transport of 1 mol of Na^+ ions from outside to inside a cell, assuming there is no Na^+ concentration gradient. Since both forces do in fact act on Na^+ ions, the total ΔG is the sum of the two partial values:

$$\Delta G = \Delta G_c + \Delta G_m = (-1.45) + (-1.61) = -3.06 \text{ kcal/mole}$$

In this example, the Na^+ concentration gradient and the membrane electric potential contribute almost equally to the total ΔG for transport of Na^+ ions. Since ΔG is <0 , the inward movement of Na^+ ions is thermodynamically favored. As discussed in the next section, the inward movement of Na^+ is used to power the uphill movement of other ions and several types of small molecules into or out of animal cells. The rapid, energetically favorable movement of Na^+ ions through gated Na^+ channels also is critical in generating action potentials in nerve and muscle cells, as we discuss in Chapter 22.

Na^+ -Linked Symporters Enable Animal Cells to Import Glucose and Amino Acids Against High Concentration Gradients

Most body cells import glucose from the blood *down* a concentration gradient of glucose, utilizing GLUT proteins to facilitate this transport. However, certain cells, such as those

FIGURE 11-25 Transmembrane forces acting on Na⁺ ions.

As with all ions, the movement of Na⁺ ions across the plasma membrane is governed by the sum of two separate forces—the ion concentration gradient and the membrane electric potential. At the internal and external Na⁺ concentrations typical of mammalian cells, these forces usually act in the same direction, making the inward movement of Na⁺ ions energetically favorable.

lining the small intestine and the kidney tubules, need to import glucose from extracellular fluids (digestive products or urine) against a very large concentration gradient (glucose concentration higher inside the cell). Such cells utilize a *two-Na⁺/one-glucose symporter*, a protein that couples import of one glucose molecule to the import of two Na⁺ ions:

Quantitatively, the free-energy change for the symport transport of two Na⁺ ions and one glucose molecule can be written

$$\Delta G = RT \ln \frac{[\text{glucose}_{\text{in}}]}{[\text{glucose}_{\text{out}}]} + 2RT \ln \frac{[\text{Na}^+_{\text{in}}]}{[\text{Na}^+_{\text{out}}]} + 2FE \quad (11-7)$$

Thus the ΔG for the overall reaction is the sum of the free-energy changes generated by the glucose concentration gradient (1 molecule transported), the Na⁺ concentration gradient (2 Na⁺ ions transported), and the membrane potential (2 Na⁺ ions transported). As illustrated in Figure 11-25, the free energy released by movement of 1 mole of Na⁺ ions into mammalian cells down its electrochemical gradient has a free-energy change, ΔG , of about -3 kcal per mole of Na⁺ transported. Thus the ΔG for transport of two moles of Na⁺ inward would be twice this amount, or about -6 kcal . This negative free-energy change of sodium import is coupled to the uphill transport of glucose, a process with a positive ΔG . We can calculate the glucose concentration gradient, inside greater than outside, that can be established by the action of this Na⁺-powered symporter by realizing that at equilibrium for sodium-coupled glucose import, $\Delta G = 0$. By substituting the values for sodium import into Equation 11-7 and setting $\Delta G = 0$, we see that

$$0 = RT \ln \frac{[\text{glucose}_{\text{in}}]}{[\text{glucose}_{\text{out}}]} - 6 \text{ kcal}$$

and we can calculate that at equilibrium, the ratio of $\text{glucose}_{\text{in}}/\text{glucose}_{\text{out}} = \sim 30,000$. Thus the inward flow of two moles of Na⁺ can generate an intracellular glucose concentration that is $\sim 30,000$ times greater than the exterior concentration. If only one Na⁺ ion were imported (ΔG of approximately -3 kcal/mol) per glucose molecule, then the available energy could generate a glucose concentration gradient (inside/outside) of only about 170-fold. Thus by coupling the transport of two Na⁺ ions to the transport of one glucose, the two-Na⁺/

one-glucose symporter permits cells to accumulate a very high concentration of glucose relative to the external concentration. This means that glucose present even at very low concentrations in the lumen of the intestine or in the kidney tubules can be efficiently transported into the lining cells and not lost from the body.

The two-Na⁺/one-glucose symporter is thought to contain 14 transmembrane α helices with both its N- and C-termini extending into the cytosol. A truncated recombinant protein consisting of only the five C-terminal transmembrane α helices can transport glucose independently of Na⁺ across the plasma membrane, *down* its concentration gradient. This portion of the molecule thus functions as a glucose uniporter. The N-terminal portion of the protein, including helices 1–9, is required to couple Na⁺ binding and influx to the transport of glucose against a concentration gradient.

Figure 11-26 depicts the current model of transport by Na⁺/glucose symporters. This model entails conformational changes in the protein analogous to those that occur in uniport transporters, such as GLUT1, which do not require a cotransported ion (compare to Figure 11-5). Binding of all substrates to their sites on the extracellular domain is required before the protein undergoes the conformational change that converts the substrate-binding sites from outward to inward facing; this ensures that inward transport of glucose and Na⁺ ions are coupled.

Note that cells use comparable Na⁺-powered symporters to transport substances other than glucose into the cell against high concentration gradients. For example, several types of Na⁺/amino acid symporters allow cells to import many amino acids into the cell.

FIGURE 11-26 Operational model for the two- Na^+ /one-glucose symporter. Simultaneous binding of Na^+ and glucose to the conformation with outward-facing binding sites (step **1**) causes a conformational change in the protein such that the bound substrates are transiently occluded, unable to dissociate into either medium (step **2**). In step **3** the protein assumes a third conformation with inward-facing

sites. Dissociation of the bound Na^+ and glucose into the cytosol (step **4**) allows the protein to revert to its original outward-facing conformation (step **5**), ready to transport additional substrate. [See H. Krishnamurthy et al., 2009, *Nature* **459**:347–355 for details on the structure and function of this and related Na^+ -coupled transporters.]

A Bacterial Na^+ /Amino Acid Symporter Reveals How Symport Works

No three-dimensional structure has yet been determined for any mammalian sodium symporter, but the structures of several homologous bacterial sodium/substrate symporters have provided considerable information about symport function. The bacterial two- Na^+ /one-leucine symporter shown in Figure 11-27a consists of 12 membrane-spanning α helices. Two of the helices (numbers 1 and 6) have nonhelical segments in the middle of the membrane that form part of the leucine-binding site.

Amino acid residues involved in binding the leucine and the two Na^+ ions are located in the middle of the membrane-spanning segment (as depicted for the two- Na^+ /one-glucose symporter in Figure 11-26) and are close together in three-dimensional space. This demonstrates that the coupling of amino acid and ion transport in these transporters is the consequence of direct or nearly direct physical interactions of the substrates. Indeed, one of the Na^+ ions is bound to the carboxyl group of the transported leucine (Figure 11-27b). Thus neither substance can bind to the transporter without the other, indicating how transport of sodium and leucine are coupled. Each of the two Na^+ ions is bound to six oxygen atoms. Sodium 1, for example, is bound to carbonyl oxygens of several transporter amino acids as well as to carbonyl oxygens and the hydroxyl oxygen of one threonine. Equally importantly, there are no water molecules surrounding either of the bound Na^+ atoms, as is the case for K^+ ions in potassium channels (see Figure 11-21). Thus as the Na^+ ions lose their water of hydration in binding to the transporter, they bind to six oxygen atoms with a similar geometry. This reduces the energy change required for binding of Na^+ ions and prevents other ions, such as K^+ , from binding in place of Na^+ .

One striking feature of the structure depicted in Figure 11-27 is that the bound Na^+ ions and leucine are *occluded*—that is, they cannot diffuse out of the protein to either the

surrounding extracellular or cytoplasmic media. This structure represents an intermediate in the transport process (see Figure 11-26) in which the protein appears to be changing from a conformation with an exoplasmic- to one with a cytosolic-facing binding site.

A Na^+ -Linked Ca^{2+} Antiporter Regulates the Strength of Cardiac Muscle Contraction

In all muscle cells, a rise in the cytosolic Ca^{2+} concentration triggers contraction. In cardiac muscle cells a *three- Na^+ /one- Ca^{2+} antiporter*, rather than the plasma membrane Ca^{2+} ATPase discussed earlier, plays the principal role in maintaining a low concentration of Ca^{2+} in the cytosol. The transport reaction mediated by this *cation antiporter* can be written

Note that the inward movement of three Na^+ ions is required to power the export of one Ca^{2+} ion from the cytosol, with a $[\text{Ca}^{2+}]$ of $\sim 2 \times 10^{-7} \text{ M}$, to the extracellular medium, with a $[\text{Ca}^{2+}]$ of $\sim 2 \times 10^{-3} \text{ M}$, a gradient of some 10,000-fold (higher on the outside). By lowering cytosolic Ca^{2+} , operation of the $\text{Na}^+/\text{Ca}^{2+}$ antiporter reduces the strength of heart muscle contraction.

 The Na^+/K^+ ATPase in the plasma membrane of cardiac muscle cells, as in other body cells, creates the Na^+ concentration gradient necessary for export of Ca^{2+} by the Na^+ -linked Ca^{2+} antiporter. As mentioned earlier, inhibition of the Na^+/K^+ ATPase by the drugs ouabain and digoxin lowers the cytosolic K^+ concentration and, more relevant here, simultaneously increases cytosolic Na^+ . The resulting reduced Na^+ electrochemical gradient across the membrane causes the Na^+ -linked Ca^{2+} antiporter to function less efficiently. As a result, fewer Ca^{2+} ions are exported and the

FIGURE 11-27 Three-dimensional structure of the two- Na^+ /one-leucine symporter from the bacterium *Aquifex aeolicus*. (a) The bound L-leucine, two Na^+ ions, and a Cl^- ion are shown in yellow, purple and green, respectively. The three membrane-spanning α helices that bind the Na^+ or leucine are colored brown, blue, and orange. (b,c) Binding of the two Na^+ ions to carbonyl main-chain

oxygen atoms or carboxyl side-chain oxygens (red) that are part of helices 1 (brown), 6 (blue), or 8 (orange). It is important that one of the sodium ions is also bound to the carboxyl group of the transported leucine (part b). [From A. Yamashita et al., 2005, *Nature* **437**:215; see also H. Krishnamurthy et al., 2009, *Nature* **459**:347–355 for details on the structure and function of this and related Na^+ -coupled transporters.]

cytosolic Ca^{2+} concentration increases, causing the muscle to contract more strongly. Because of their ability to increase the force of heart muscle contractions, drugs such as ouabain and digoxin that inhibit the Na^+/K^+ ATPase are widely used in the treatment of congestive heart failure. ■

Several Cotransporters Regulate Cytosolic pH

The anaerobic metabolism of glucose yields lactic acid, and aerobic metabolism yields CO_2 , which combines with water to form carbonic acid (H_2CO_3). These weak acids dissociate, yielding H^+ ions (protons); if these excess protons were not removed from cells, the cytosolic pH would drop precipitously, endangering cellular functions. Two types of cotransport proteins help remove some of the “excess” protons generated during metabolism in animal cells. One is a $\text{Na}^+/\text{HCO}_3^-/\text{Cl}^-$ antiporter, which imports one Na^+ ion together with one HCO_3^- , in exchange for export of one Cl^- ion. The cytosolic enzyme *carbonic anhydrase* catalyzes dissocia-

tion of the imported HCO_3^- ions into CO_2 and an OH^- (hydroxyl) ion:

The OH^- ions combine with intracellular protons, forming water, and the CO_2 diffuses out of the cell. Thus the overall action of this transporter is to *consume* cytosolic H^+ ions, thereby *raising* the cytosolic pH. Also important in raising cytosolic pH is a Na^+/H^+ antiporter, which couples entry of one Na^+ ion into the cell down its concentration gradient to the export of one H^+ ion.

Under certain circumstances, the cytosolic pH can rise beyond the normal range of 7.2–7.5. To cope with the excess OH^- ions associated with elevated pH, many animal cells utilize an *anion antiporter* that catalyzes the one-for-one exchange of HCO_3^- and Cl^- across the plasma membrane. At high pH, this $\text{Cl}^-/\text{HCO}_3^-$ antiporter exports one molecule of

HCO_3^- (which can be viewed as a “complex” of OH^- and CO_2) in exchange for import of one molecule of Cl^- , thus lowering the cytosolic pH. The import of Cl^- down its concentration gradient ($\text{Cl}^-_{\text{medium}} > \text{Cl}^-_{\text{cytosol}}$; see Table 11-2) powers the export of HCO_3^- .

The activity of all three of these antiport proteins is regulated by the cytosolic pH, providing cells with a finely tuned mechanism for controlling cytosolic pH. The two antiporters that operate to increase cytosolic pH are activated when the pH of the cytosol falls. Similarly, a rise in pH above 7.2 stimulates the $\text{Cl}^-/\text{HCO}_3^-$ antiporter, leading to a more rapid export of HCO_3^- and a drop in the cytosolic pH. In this manner, the cytosolic pH of growing cells is maintained very close to pH 7.4.

An Anion Antiporter Is Essential for Transport of CO_2 by Red Blood Cells

Transmembrane anion exchange is essential for an important function of erythrocytes—the transport of waste CO_2 from peripheral tissues to the lungs for exhalation. Waste CO_2 released from cells into the capillary blood freely diffuses across the erythrocyte membrane (Figure 11-28a). In its gaseous form, CO_2 dissolves poorly in aqueous solutions, such as the cytosol or blood plasma, as is apparent to anyone who has opened a bottle of a carbonated beverage. However, the large amount of the potent enzyme carbonic anhydrase inside the erythrocyte combines CO_2 with hydroxyl ions (OH^-) to form water-soluble bicarbonate (HCO_3^-) anions. This process occurs while red cells are in systemic (tissue) capillaries and releasing oxygen into the blood plasma. Release of oxygen from hemoglobin induces a change in its

conformation that enables a histidine side chain of a globin polypeptide to bind a proton. Thus when red cells are in systemic capillaries water is split into a proton that binds hemoglobin and an OH^- that reacts with CO_2 to form an HCO_3^- anion.

In a reaction catalyzed by the red cell antiporter AE1, cytosolic HCO_3^- is transported out of the erythrocyte in exchange for an entering Cl^- anion:

(see Figure 11-28a). The entire anion-exchange process is completed within 50 milliseconds (ms), during which time 5×10^9 HCO_3^- ions are exported from each cell down its concentration gradient. If anion exchange did not occur, during periods such as exercise, when much CO_2 is generated, HCO_3^- would accumulate inside the erythrocyte to toxic levels as the cytosol would become alkaline. The exchange of HCO_3^- (equal to $\text{OH}^- + \text{CO}_2$) for Cl^- causes the cytosolic pH to remain nearly neutral. Normally about 80 percent of the CO_2 in blood is transported as HCO_3^- generated inside erythrocytes; anion exchange allows about two-thirds of this HCO_3^- to be transported by blood plasma external to the cells, increasing the amount of CO_2 that can be transported from tissues to the lungs. In the lungs, where carbon dioxide leaves the body, the overall direction of this anion-exchange process is reversed (Figure 11-28b).

AE1 catalyzes the precise one-for-one sequential exchange of anions on opposite sides of the membrane required to preserve electroneutrality in the cell; only once every 10,000 or so transport cycles does an anion move unidirectionally from one side of the membrane to the other. AE1 is

FIGURE 11-28 Carbon dioxide transport in blood requires a $\text{Cl}^-/\text{HCO}_3^-$ antiporter. (a) In systemic capillaries, carbon dioxide gas diffuses across the erythrocyte plasma membrane and is converted into soluble HCO_3^- by the enzyme carbonic anhydrase; at the same time, oxygen leaves the cell and hemoglobin binds a proton. The anion antiporter AE1 (purple) catalyzes the reversible exchange of Cl^- and

HCO_3^- ions across the membrane. The overall reaction causes HCO_3^- to be released from the cell, which is essential for maximal CO_2 transport from the tissues to the lungs, and for maintaining pH neutrality in the blood cell. (b) In the lungs, where carbon dioxide is excreted, the overall reaction is reversed. See text for additional discussion.

composed of a membrane-embedded domain, folded into at least 12 transmembrane α helices, that catalyzes anion transport, and a cytosolic-facing domain that anchors certain cytoskeletal proteins to the membrane (see Figure 17-21).

Numerous Transport Proteins Enable Plant Vacuoles to Accumulate Metabolites and Ions

The lumen of plant vacuoles is much more acidic (pH 3–6) than is the cytosol (pH 7.5). The acidity of vacuoles is maintained by a V-class ATP-powered proton pump (see Figure 11-9) and by a pyrophosphate-powered proton pump that is unique to plants. Both of these pumps, located in the vacuolar membrane, import H^+ ions into the vacuolar lumen against a concentration gradient. The vacuolar membrane also contains Cl^- and NO_3^- channels that transport these anions from the cytosol into the vacuole. Entry of these anions against their concentration gradients is driven by the inside-positive potential generated by the H^+ pumps. The combined operation of these proton pumps and anion channels produces an inside-positive electric potential of about 20 mV across the vacuolar membrane and also a substantial pH gradient (Figure 11-29).

FIGURE 11-29 Concentration of ions and sucrose by the plant vacuole. The vacuolar membrane contains two types of proton pumps (orange): a V-class H^+ ATPase (left) and a pyrophosphate-hydrolyzing proton pump (right) that differs from all other ion transport proteins and probably is unique to plants. These pumps generate a low luminal pH as well as an inside-positive electric potential across the vacuolar membrane owing to the inward pumping of H^+ ions. The inside-positive potential powers the movement of Cl^- and NO_3^- from the cytosol through separate channel proteins (purple). Proton antiporters (green), powered by the H^+ gradient, accumulate Na^+ , Ca^{2+} , and sucrose inside the vacuole. [After B. J. Barkla and O. Pantoja, 1996, *Rev. Plant Physiol. Plant Mol. Biol.* 47:159–184 and P. A. Rea et al., 1992, *Trends Biochem. Sci.* 17:348.]

The proton electrochemical gradient across the plant vacuole membrane is used in much the same way as the Na^+ electrochemical gradient across the animal-cell plasma membrane: to power the selective uptake or extrusion of ions and small molecules by various antiporters. In the leaf, for example, excess sucrose generated during photosynthesis in the day is stored in the vacuole; during the night, the stored sucrose moves into the cytoplasm and is metabolized to CO_2 and H_2O with concomitant generation of ATP from ADP and P_i . A *proton/sucrose antiporter* in the vacuolar membrane operates to accumulate sucrose in plant vacuoles. The inward movement of sucrose is powered by the outward movement of H^+ , which is favored by its concentration gradient (lumen $>$ cytosol) and by the cytosolic-negative potential across the vacuolar membrane (see Figure 11-29). Uptake of Ca^{2+} and Na^+ into the vacuole from the cytosol against their concentration gradients is similarly mediated by proton antiporters.

 Understanding of the transport proteins in plant vacuolar membranes has the potential for increasing agricultural production in high-salt (NaCl) soils, which are found throughout the world. Because most agriculturally useful crops cannot grow in such saline soils, agricultural scientists have long sought to develop salt-tolerant plants by traditional breeding methods. With the availability of the cloned gene encoding the vacuolar Na^+/H^+ antiporter, researchers can now produce transgenic plants that overexpress this transport protein, leading to increased sequestration of Na^+ in the vacuole. For instance, transgenic tomato plants that overexpress the vacuolar Na^+/H^+ antiporter can grow, flower, and produce fruit in the presence of soil NaCl concentrations that kill wild-type plants. Interestingly, although the leaves of these transgenic tomato plants accumulate large amounts of salt, the fruit has a very low salt content. ■

KEY CONCEPTS of Section 11.5

Cotransport by Symporters and Antiporters

- The electrochemical gradient across a semipermeable membrane determines the direction of ion movement through transmembrane proteins. The two forces constituting the electrochemical gradient—the membrane electric potential and the ion concentration gradient—may act in the same or opposite directions (see Figure 11-25).
- Cotransporters use the energy released by movement of an ion (usually H^+ or Na^+) down its electrochemical gradient to power the import or export of a small molecule or different ion against its concentration gradient.
- The cells lining the small intestine and kidney tubules contain symport proteins that couple the energetically favorable entry of Na^+ to the import of glucose against its concentration gradient (see Figure 11-26). Amino acids also enter cells by Na^+ -coupled symporters.

- The molecular structure of a bacterial Na^+ /amino acid symporter reveals how binding of Na^+ and leucine are coupled and provides a snapshot of an occluded transport intermediate in which the bound substrates cannot diffuse out of the protein (see Figure 11-27).

- In cardiac muscle cells, the export of Ca^{2+} is coupled to and powered by the import of Na^+ by a cation antiporter, which transports three Na^+ ions inward for each Ca^{2+} ion exported.

- Two cotransporters that are activated at low pH help maintain the cytosolic pH in animal cells very close to 7.4 despite metabolic production of carbonic and lactic acids. One, a Na^+/H^+ antiporter, exports excess protons. The other, a $\text{Na}^+\text{HCO}_3^-/\text{Cl}^-$ cotransporter, imports HCO_3^- , which dissociates in the cytosol to yield pH-raising OH^- ions.

- A $\text{Cl}^-/\text{HCO}_3^-$ antiporter that is activated at high pH functions to export HCO_3^- when the cytosolic pH rises above normal and causes a decrease in pH.

- AE1, a $\text{Cl}^-/\text{HCO}_3^-$ antiporter in the erythrocyte membrane, increases the ability of blood to transport CO_2 from tissues to the lungs (see Figure 11-28).

- Uptake of sucrose, Na^+ , Ca^{2+} , and other substances into plant vacuoles is carried out by proton antiporters in the vacuolar membrane. Ion channels and proton pumps in the membrane are critical in generating a large enough proton concentration gradient to power accumulation of ions and metabolites in vacuoles by these proton antiporters (see Figure 11-29).

11.6 Transcellular Transport

Previous sections illustrated how several types of transporters function together to carry out important cell functions. Here, we extend this concept by focusing on the transport of several types of molecules and ions across polarized cells, which are cells that are asymmetric (have different “sides”) and thus have biochemically distinct regions of the plasma membrane. A particularly well-studied class of polarized cells are the epithelial cells that form sheetlike layers (epithelia) covering most external and internal surfaces of body organs. Epithelial cells are discussed in greater detail in Chapter 20. Like many epithelial cells, an intestinal epithelial cell involved in absorbing nutrients from the gastrointestinal tract has a plasma membrane organized into two major discrete regions: the surface that faces the outside of the organism, called the **apical**, or top, surface, and the surface that faces the inside (or bloodstream-facing side) of the organism, called the **basolateral** surface (see Figure 20-10).

Specialized regions of the epithelial-cell plasma membrane, called **tight junctions**, separate the apical and basolateral membranes and prevent many, but not all, water-soluble substances on one side from moving across to the other side through the extracellular space between cells. For this rea-

FIGURE 11-30 Transcellular transport of glucose from the intestinal lumen into the blood. The Na^+/K^+ ATPase in the basolateral surface membrane generates Na^+ and K^+ concentration gradients (step 1). The outward movement of K^+ ions through nongated K^+ channels generates an inside-negative membrane potential across the entire plasma membrane. Both the Na^+ concentration gradient and the membrane potential are used to drive the uptake of glucose from the intestinal lumen by the two- Na^+ /one-glucose symporter located in the apical surface membrane (step 2). Glucose leaves the cell via facilitated diffusion catalyzed by GLUT2, a glucose uniporter located in the basolateral membrane (step 3).

son, absorption of many nutrients from the intestinal lumen across the epithelial cell layer and eventually into the blood occurs by the two-stage process called **transcellular transport**: import of molecules through the plasma membrane on the apical side of intestinal epithelial cells and their export through the plasma membrane on the basolateral (blood-facing) side (Figure 11-30). The apical portion of the plasma membrane, which faces the intestinal lumen, is specialized for absorption of sugars, amino acids, and other molecules that are produced from food by multiple digestive enzymes.

Multiple Transport Proteins Are Needed to Move Glucose and Amino Acids Across Epithelia

Figure 11-30 depicts the proteins that mediate absorption of glucose from the intestinal lumen into the blood and illustrates the important concept that different types of proteins are localized to the apical and basolateral membranes of epithelial cells. In the first stage of this process, a two- Na^+ /one-glucose symporter located in the apical membrane imports glucose, against its concentration gradient, from the intestinal lumen across the apical surface of the epithelial cells. As noted above, this symporter couples the energetically unfavorable inward movement of one glucose molecule to the energetically favorable inward transport of two Na^+ ions (see Figure 11-26). In the steady state, all the Na^+ ions transported from the intestinal lumen into the cell during

Na^+ /glucose symport, or the similar process of Na^+ /amino acid symport that also takes place on the apical membrane, are pumped out across the basolateral membrane, which faces the blood. Thus the low intracellular Na^+ concentration is maintained. The Na^+/K^+ ATPase that accomplishes this is found exclusively in the basolateral membrane of intestinal epithelial cells. The coordinated operation of these two transport proteins allows uphill movement of glucose and amino acids from the intestine into the cell. This first stage in transcellular transport ultimately is powered by ATP hydrolysis by the Na^+/K^+ ATPase.

In the second stage, glucose and amino acids concentrated inside intestinal cells by apical symporters are exported down their concentration gradients into the blood via uniport proteins in the basolateral membrane. In the case of glucose, this movement is mediated by GLUT2 (see Figure 11-30). As noted earlier, this GLUT isoform has a relatively low affinity for glucose but increases its rate of transport substantially when the glucose gradient across the membrane rises (see Figure 11-4).

The net result of this two-stage process is movement of Na^+ ions, glucose, and amino acids from the intestinal lumen across the intestinal epithelium into the extracellular medium that surrounds the basolateral surface of intestinal epithelial cells, and eventually into the blood. Tight junctions between the epithelial cells prevent these molecules from diffusing back into the intestinal lumen. The increased osmotic pressure created by transcellular transport of salt, glucose, and amino acids across the intestinal epithelium draws water from the intestinal lumen, mainly through the tight junctions, into the extracellular medium that surrounds the basolateral surface; aquaporins do not appear to play a major role. In a sense, salts, glucose, and amino acids “carry” the water along with them.

Simple Rehydration Therapy Depends on the Osmotic Gradient Created by Absorption of Glucose and Na^+

 An understanding of osmosis and the intestinal absorption of salt and glucose forms the basis for a simple therapy that saves millions of lives each year, particularly in less-developed countries. In these countries, cholera and other intestinal pathogens are major causes of death of young children. A toxin released by the bacteria activates chloride secretion from the apical surface of the intestinal epithelial cells into the lumen; water follows osmotically, and the resultant massive loss of water causes diarrhea, dehydration, and ultimately death. A cure demands not only killing the bacteria with antibiotics but also *rehydration*—replacement of the water that is lost from the blood and other tissues.

Simply drinking water does not help, because it is excreted from the gastrointestinal tract almost as soon as it enters. However, as we have just learned, the coordinated transport of glucose and Na^+ across the intestinal epithelium creates a transepithelial osmotic gradient, forcing movement of water from the intestinal lumen across the epithelial cell

layer and ultimately into the blood. Thus giving affected children a solution of sugar and salt to drink (but not sugar or salt alone) causes increased sodium and sugar transepithelial transport and consequently increased osmotic flow of water into the blood from the intestinal lumen, leading to rehydration. Similar sugar-salt solutions are the basis of popular drinks used by athletes to get sugar as well as water into the body quickly and efficiently. ■

Parietal Cells Acidify the Stomach Contents While Maintaining a Neutral Cytosolic pH

The mammalian stomach contains a 0.1 M solution of hydrochloric acid (HCl). This strongly acidic medium kills many ingested pathogens and denatures many ingested proteins so that they can be degraded by proteolytic enzymes (e.g., pepsin) that function at acidic pH. Hydrochloric acid is secreted into the stomach by specialized epithelial cells called *parietal cells* (also known as *oxyntic cells*) in the stomach lining. These cells contain an H^+/K^+ ATPase in their apical membrane, which faces the stomach lumen and generates a millionfold H^+ concentration gradient: pH ~ 1.0 in the stomach lumen versus pH ~ 7.2 in the cell cytosol. This transport protein is a P-class ATP-powered ion pump similar in structure and function to the plasma membrane Na^+/K^+ ATPase discussed earlier. The numerous mitochondria in parietal cells produce abundant ATP for use by the H^+/K^+ ATPase.

If parietal cells simply exported H^+ ions in exchange for K^+ ions, the loss of protons would lead to a rise in the concentration of OH^- ions in the cytosol and thus a marked increase in cytosolic pH. (Recall that $[\text{H}^+] \times [\text{OH}^-]$ always is a constant, 10^{-14} M^2 .) Parietal cells avoid this rise in cytosolic pH in conjunction with acidification of the stomach lumen by using $\text{Cl}^-/\text{HCO}_3^-$ antiporters in the basolateral membrane to export the “excess” OH^- ions from the cytosol to the blood. As noted earlier, this anion antiporter is activated at high cytosolic pH.

The overall process by which parietal cells acidify the stomach lumen is illustrated in Figure 11-31. In a reaction catalyzed by carbonic anhydrase, the “excess” cytosolic OH^- combines with CO_2 that diffuses in from the blood, forming HCO_3^- . Catalyzed by the basolateral anion $\text{Cl}^-/\text{HCO}_3^-$ antiporter, this bicarbonate ion is exported across the basolateral membrane (and ultimately into the blood) in exchange for a Cl^- ion. The Cl^- ions then exit through Cl^- channels in the apical membrane, entering the stomach lumen. To preserve electroneutrality, each Cl^- ion that moves into the stomach lumen across the apical membrane is accompanied by a K^+ ion that moves outward through a separate K^+ channel. In this way, the excess K^+ ions pumped inward by the H^+/K^+ ATPase are returned to the stomach lumen, thus maintaining the normal intracellular K^+ concentration. The net result is secretion of equal amounts of H^+ and Cl^- ions (i.e., HCl) into the stomach lumen, while the pH of the cytosol remains neutral and the excess OH^- ions, as HCO_3^- , are transported into the blood.

FIGURE 11-31 Acidification of the stomach lumen by parietal cells in the gastric lining. The apical membrane of parietal cells contains an H^+/K^+ ATPase (a P-class pump) as well as Cl^- and K^+ channel proteins. Note the cyclic K^+ transport across the apical membrane: K^+ ions are pumped inward by the H^+/K^+ ATPase and exit via a K^+ channel. The basolateral membrane contains an anion antiporter that exchanges HCO_3^- and Cl^- ions. The combined operation of these four different transport proteins and carbonic anhydrase acidifies the stomach lumen while maintaining the neutral pH of the cytosol.

Bone Resorption Requires Coordinated Function of a V-Class Proton Pump and a Specific Chloride Channel Protein

Net bone growth in mammals subsides just after puberty, but a finely balanced, highly dynamic process of disassembly (resorption) and reassembly (bone formation) goes on throughout adulthood. Such continual bone *remodeling* permits the repair of damaged bones and can release calcium, phosphate, and other ions from mineralized bone into the blood for use elsewhere in the body.

Osteoclasts, the bone-dissolving cells, are a type of macrophage best known for their role in protecting the body from infections. Osteoclasts are polarized cells that form specialized, very tight seals between themselves and bone, creating an enclosed extracellular space (Figure 11-32). An adhered osteoclast then secretes into this space a corrosive mixture of HCl and proteases that dissolves the inorganic components of the bone into Ca^{2+} and phosphate and digests its protein components. The mechanism of HCl secretion is similar to that used by the stomach to generate digestive juice (see Figure 11-31). As in gastric HCl secretion, carbonic anhydrase and an anion antiport protein are important for osteoclast function. Osteoclasts employ a V-type proton pump to export H^+ ions into the bone-facing space rather than the P-class ATP-powered H^+/K^+ pump used by gastric epithelial cells

The rare hereditary disease *osteopetrosis*, marked by increased bone density, is due to abnormally low bone

FIGURE 11-32 Dissolution of bone by polarized osteoclast cells requires a V-class proton pump and the ClC-7 chloride channel protein. The osteoclast plasma membrane is divided into two domains separated by the tight seal between a ring of membrane and the bone surface. The membrane domain facing the bone contains V-class proton pumps and ClC-7 Cl^- channels. The opposing membrane domain contains anion antiporters that exchange HCO_3^- and Cl^- ions. The combined operation of these three transport proteins and carbonic anhydrase acidifies the enclosed space and allows bone resorption while maintaining the neutral pH of the cytosol.

[See R. Planells-Cases and T. Jentsch, 2009, *Biochim. Biophys. Acta* **1792**:173 for discussion of ClC-7.]

resorption. Many patients have an inactivating mutation in the gene encoding ClC-7, the chloride channel protein localized to the domain of the osteoclast plasma membrane that faces the space near the bone. As with lysosomes (see Figure 11-14), in the absence of a chloride channel the proton pump cannot acidify the enclosed extracellular space and thus bone resorption is defective. ■

KEY CONCEPTS of Section 11.6

Transcellular Transport

- The apical and basolateral plasma membrane domains of epithelial cells contain different transport proteins and carry out quite different transport processes.
- In the intestinal epithelial cell, the coordinated operation of Na^+ -linked symporters in the apical membrane and Na^+/K^+ ATPases and uniporters in the basolateral membrane mediates transcellular transport of amino acids and glucose from the intestinal lumen to the blood (see Figure 11-30).
- The increased osmotic pressure created by transcellular transport of salt, glucose, and amino acids across the intestinal epithelium draws water from the intestinal lumen into the body, a phenomenon that serves as the basis for rehydration therapy using sugar-salt solutions.
- The combined action of carbonic anhydrase and four different transport proteins permits parietal cells in the stomach

lining to secrete HCl into the lumen while maintaining their cytosolic pH near neutrality (see Figure 11-31).

- Bone resorption requires coordinated function in osteoclasts of a V-class proton pump and the ClC-7 chloride channel protein (Figure 11-32).

Perspectives for the Future

In this chapter, we have explained the action of specific membrane transport proteins and their impact on certain aspects of human physiology; such a molecular physiology approach has many medical applications. Even today, specific inhibitors or activators of channels, pumps, and transporters constitute the largest single class of drugs. For instance, an inhibitor of the gastric H^+/K^+ ATPase that acidifies the stomach is the most widely used drug for treating stomach ulcers and gastric reflux syndrome. Inhibitors of channel proteins in the kidney are widely used to control hypertension (high blood pressure); by blocking resorption of water into the blood from urine forming in the kidneys, these drugs reduce blood volume and thus blood pressure. Calcium-channel blockers are widely employed to control the intensity of contraction of the heart. Drugs that inhibit a particular potassium channel in β islet cells enhance secretion of insulin (see Figure 16-38), and are widely used to treat adult-onset (type II) diabetes.

With the completion of the human genome project, we have in hand the sequences of all human membrane-transport proteins. Already we know that mutations in many of them cause disease—cystic fibrosis, due to mutations in CFTR, is one example, and osteopetrosis, caused by mutations in the ClC-7 chloride channel, is another. More recently it was shown that loss-of-function mutations in either subunit of a different chloride channel, ClC-K, cause both salt loss by the kidney and deafness. This explosion of basic knowledge, associating specific genetic diseases with specific transport proteins, will enable researchers to identify new types of compounds that inhibit or activate just one of these membrane transport proteins and not its homologs. An important challenge, however, is to understand the role of an individual transport protein in each of the several tissues in which it is expressed.

Another major challenge is to understand how each channel, transporter, and pump is regulated to meet the needs of the cell. Like other cellular proteins, many of these proteins undergo reversible phosphorylation, ubiquitination, and other covalent modifications that affect their activity, but in the vast majority of cases, we do not understand how this regulation affects cellular function. Many channels, transporters, and pumps normally reside on intracellular membranes, not on the plasma membrane, and move to the plasma membrane only when a particular hormone is present. The addition of insulin to muscle, for instance, causes the GLUT4 glucose transporter to move from intracellular membranes to the plasma membrane, increasing the rate of glucose uptake. We noted earlier that the addition of vaso-

pressin to certain kidney cells similarly causes an aquaporin to traffic to the plasma membrane, increasing the rate of water transport. But despite much research, the underlying cellular mechanisms by which hormones stimulate the movement of transport proteins to and from the plasma membrane, and the regulation of these processes, remain obscure.

Key Terms

ABC superfamily 485	membrane potential 475
active transport 476	Na^+/K^+ ATPase 489
antiport 502	patch clamping 500
aquaporins 480	P-class pump 484
ATP-powered pump 476	resting K^+ channel 497
cotransport 502	resting potential 495
electrochemical gradient 475	sarcoplasmic reticulum 486
facilitated transport 476	simple diffusion 474
F-class pump 484	symport 502
flippase 493	tight junction 508
gated channel 476	transporter 476
GLUT proteins 479	transcellular transport 508
hypertonic 481	uniport 478
hypotonic 481	V-class pump 484
isotonic 481	

Review the Concepts

1. Nitric oxide (NO) is a gaseous molecule with lipid solubility similar to that of O_2 and CO_2 . Endothelial cells lining arteries use NO to signal surrounding smooth muscle cells to relax, thereby increasing blood flow. What mechanism or mechanisms would transport NO from where it is produced in the cytoplasm of an endothelial cell into the cytoplasm of a smooth muscle cell where it acts?
2. Acetic acid (a weak acid with a pK_a of 4.75) and ethanol (an alcohol) are each composed of two carbons, hydrogen, and oxygen, and both enter cells by passive diffusion. At pH 7, one is much more membrane permeable than the other. Which is more permeable and why? Predict how the permeability of each is altered when the pH is reduced to 1.0, a value typical of the stomach.
3. Uniporters and ion channels support facilitated diffusion across biomembranes. Although both are examples of facilitated diffusion, the rates of ion movement via an ion channel are roughly 10^4 - to 10^5 -fold faster than that of molecule movement via a uniporter. What key mechanistic difference results in this large difference in transport rate? What contribution to free energy (ΔG) determines the direction of transport?
4. Name the three classes of transporters. Explain which one or more of these classes is able to move glucose and which move bicarbonate (HCO_3^-) against an electrochemical gradient. In the case of bicarbonate, but not glucose, the ΔG of the transport process has two terms. What are these two

terms, and why does the second not apply to glucose? Why are cotransporters often referred to as examples of secondary active transport?

5. An H^+ ion is smaller than an H_2O molecule, and a glycerol molecule, a three-carbon alcohol, is much larger. Both readily dissolve in H_2O . Why do aquaporins fail to transport H^+ whereas some can transport glycerol?

6. GLUT1, found in the plasma membrane of erythrocytes, is a classic example of a uniporter.

a. Design a set of experiments to prove that GLUT1 is indeed a glucose-specific uniporter rather than a galactose- or mannose-specific uniporter.

b. Glucose is a 6-carbon sugar while ribose is a 5-carbon sugar. Despite this smaller size, ribose is not efficiently transported by GLUT1. How can this be explained?

c. A drop in blood sugar from 5 mM to 2.8 mM or below can cause confusion and fainting. Calculate the effect of this drop on glucose transport into cells expressing GLUT1.

d. How do liver and muscle cells maximize glucose uptake without changing V_{max} ?

e. Tumor cells expressing GLUT1 often have a higher V_{max} for glucose transport than do normal cells of the same type. How could these cells increase the V_{max} ?

f. Fat and muscle cells modulate the V_{max} for glucose uptake in response to insulin signaling. How?

7. Name the four classes of ATP-powered pumps that produce active transport of ions and molecules. Indicate which of these classes transport ions only and which transport primarily small organic molecules. The initial discovery of one class of these ATP-powered pumps came from studying the transport of not a natural substrate but rather artificial substrates used as cancer chemotherapy drugs. What do investigators now think are common examples of the natural substrates of this particular class of ATP-powered pumps?

8. Explain why the coupled reaction $ATP \rightarrow ADP + P_i$ in the P-class ion pump mechanism does not involve direct hydrolysis of the phosphoanhydride bond.

9. Describe a negative feedback mechanism for controlling rising cytoplasmic Ca^{2+} concentration in cells that require rapid changes in Ca^{2+} concentration for normal functioning. How would a drug that inhibits calmodulin activity affect cytoplasmic Ca^{2+} concentration regulated by this mechanism? What would be the effect on the function of, for example, a skeletal muscle cell?

10. Certain proton pump inhibitors inhibit secretion of stomach acid and are among the most widely sold drugs in the world today. What pump does this type of drug inhibit, and where is this pump located?

11. The membrane potential in animal cells, but not in plants, depends largely on resting K^+ channels. How do these channels contribute to the resting potential? Why are these channels considered to be nongated channels? How do these channels achieve selectivity for K^+ versus Na^+ , which is smaller than K^+ ?

12. Patch clamping can be used to measure the conductance properties of individual ion channels. Describe how patch clamping can be used to determine whether or not the gene

coding for a putative K^+ channel actually codes for a K^+ or Na^+ channel.

13. Plants use the proton electrochemical gradient across the vacuole membrane to power the accumulation of salts and sugars in the organelle. This creates a hypertonic situation. Why does this not result in the plant cell swelling and bursting? Even under isotonic conditions, there is a slow leakage of ions into animal cells. How does the plasma membrane Na^+/K^+ ATPase enable animal cells to avoid osmotic lysis under isotonic conditions?

14. In the case of the bacterial sodium/leucine transporter, what is the key distinguishing feature about the bound sodium ions that ensures that other ions, particularly K^+ , do not bind?

15. Describe the symport process by which cells lining the small intestine import glucose. What ion is responsible for the transport, and what two particular features facilitate the energetically favored movement of this ion across the plasma membrane?

16. Movement of glucose from one side to the other side of the intestinal epithelium is a major example of transcellular transport. How does the Na^+/K^+ ATPase power the process? Why are tight junctions essential for the process? Why is localization of the transporters specifically in the apical and basolateral membrane crucial for transcellular transport? Rehydration supplements such as sport drinks include a sugar and a salt. Why are both important to rehydration?

Analyze the Data

Imagine that you are investigating the transepithelial transport of radioactive glucose. Intestinal epithelial cells are grown in culture to form a complete sheet so that the fluid bathing the apical domain of the cells (the apical medium) is completely separated from the fluid bathing the basolateral domain of the cells (the basolateral medium). Radioactive (^{14}C -labeled) glucose is added to the apical medium, and the appearance of radioactivity in the basolateral medium is monitored in terms of counts per minute per milliliter (cpm/ml), a measure of radioactivity per unit volume.

Treatment 1: The apical and basolateral media each contain 150 mM Na^+ (curve 1).

Treatment 2: The apical medium contains 1 mM Na^+ , and the basolateral medium contains 150 mM Na^+ (curve 2).

Treatment 3: The apical medium contains 150 mM Na^+ , and the basolateral medium contains 1 mM Na^+ (curve 3).

a. What is a likely explanation for the different results obtained in treatments 1 and 3 versus treatment 2?

In additional studies, the drug ouabain, which inhibits Na^+/K^+ ATPases, is included as noted.

Treatment 4: The apical and basolateral media contain 150 mM Na^+ and the apical media contains ouabain (curve 4).

Treatment 5: The apical and basolateral media contain 150 mM Na^+ and the basolateral media contains ouabain (curve 5).

b. What is a likely explanation for the different results obtained in treatment 4 versus treatment 5?

c. Certain natural compounds and drugs being tested as treatments for diabetes lower glucose transport in intestinal or kidney epithelial cells, and thereby lower blood sugar levels. Addition of one such drug to the apical medium yields transport similar to that in Treatment 5, whereas its addition to the basolateral medium yields transport similar to that in Treatment 4. What is the most likely target of this drug, and what is the effect on this target?

Stumbling upon Active Transport

J. Skou, 1957, *Biochem. Biophys. Acta* 23:394

In the mid-1950s Jens Skou was a young physician researching the effects of local anesthetics on isolated lipid bilayers. He needed an easily assayed membrane-associated enzyme to use as a marker in his studies. What he discovered was an enzyme critical to the maintenance of membrane potential, the Na^+/K^+ ATPase, a molecular pump that catalyzes active transport.

Background

During the 1950s many researchers around the world were actively investigating the physiology of the cell membrane, which plays a role in a number of biological processes. It was well known that the concentration of many ions differs inside and outside the cell. For example, the cell maintains a lower intracellular sodium (Na^+) concentration and higher intracellular potassium (K^+) concentration than is found outside the cell. Somehow the membrane can regulate intracellular salt concentrations. Additionally, movement of ions across cell membranes had been observed, suggesting that some sort of transport system is present. To maintain normal intracellular Na^+ and K^+ concentrations, the transport system could not rely on passive diffusion because both ions must move across the membrane against their concentration gradients. This energy-requiring process was termed active transport.

At the time of Skou's experiments, the mechanism of active transport was still unclear. Surprisingly, Skou had no intention of helping to clarify the field. He found the Na^+/K^+ ATPase completely by accident in his search for an abundant, easily measured enzyme activity associated with lipid membranes. A recent study had shown that membranes derived from squid axons contained a membrane-associated enzyme that could hydrolyze ATP. Thinking

that this would be an ideal enzyme for his purposes, Skou set out to isolate such an ATPase from a more readily available source, crab leg neurons. It was during his characterization of this enzyme that he discovered the protein's function.

The Experiment

Since the original goal of his study was to characterize the ATPase for use in subsequent studies, Skou wanted to know under what experimental conditions its activity was both robust and reproducible. As often is the case with the characterization of a new enzyme, this requires careful titration of the various components of the reaction. Before this can be done, one must be sure the system is free from outside sources of contamination.

In order to study the influence of various cations, including three that are critical for the reaction— Na^+ , K^+ , and Mg^{2+} —Skou had to make sure that no contaminating ions were brought into the reaction from another source. Therefore all buffers used in the purification of the enzyme were prepared from salts that did not contain these cations. An additional source of contaminating cations was the ATP substrate, which contains three phosphate groups, giving it an overall negative charge. Because stock solutions of ATP often included a cation to balance the charge, Skou converted the ATP used in his reactions to the acid form so that balancing cations would not affect the experiments. Once he had a well-controlled environment, he could characterize the enzyme activity. These precautions were fundamental to his discovery.

Skou first showed that his enzyme could indeed catalyze the cleavage of ATP into ADP and inorganic phosphate. He then moved on to look for the optimal conditions for this activity by varying the pH of the reaction, and

the concentrations of salts and other cofactors, which bring cations into the reaction. He could easily determine a pH optimum as well as an optimal concentration of Mg^{2+} , but optimizing Na^+ and K^+ proved to be more difficult. Regardless of the amount of K^+ added to the reaction, the enzyme was inactive without Na^+ . Similarly, without K^+ , Skou observed only a low-level ATPase activity that did not increase with increasing amounts of Na^+ .

These results suggested that the enzyme required both Na^+ and K^+ for optimal activity. To demonstrate that this was the case, Skou performed a series of experiments in which he measured the enzyme activity as he varied both the Na^+ and K^+ concentrations in the reaction (Figure 1). Although both cations clearly were required for significant activity, something interesting occurred at high concentrations of each cation. At the optimal concentration of Na^+ and K^+ , the ATPase activity reached a peak. Once at that peak, further increasing the concentration did not affect the ATPase activity. Na^+ thus behaved like a classic enzyme substrate, with increasing input leading to increased activity until a saturating concentration was achieved, at which the activity plateaued. K^+ , on the other hand, behaved differently. When the K^+ concentration was increased beyond the optimum, ATPase activity declined. Thus while K^+ was required for optimal activity, at high concentrations it inhibited the enzyme. Skou reasoned that the enzyme must have separate binding sites for Na^+ and K^+ . For optimal ATPase activity, both must be filled. However, at high concentrations K^+ could compete for the Na^+ -binding site, leading to enzyme inhibition. He hypothesized that this enzyme was involved in active transport, that is, the pumping of Na^+ out of the cell, coupled to the import of K^+ into the cell. Later studies would

FIGURE 1 Demonstration of the dependence of Na⁺/K⁺ ATPase activity on the concentration of each ion. The graph on the left shows that increasing K⁺ leads to an inhibition of the ATPase activity. The graph on the right shows that with increasing Na⁺, the enzyme activity

increases up to a peak and then levels out. This graph also demonstrates the dependence of the activity on low levels of K⁺. [Adapted from J. Skou, 1957, *Biochem. Biophys. Acta* 23:394.]

prove that this enzyme was indeed the pump that catalyzed active transport. This finding was so exciting that Skou devoted his subsequent research to studying the enzyme, never using it as a marker, as he initially intended.

Discussion

Skou's finding that a membrane ATPase used both Na⁺ and K⁺ as substrates was the first step in understanding

active transport on a molecular level. How did Skou know to test both Na⁺ and K⁺? In his Nobel lecture in 1997, he explained that in his first attempts at characterizing the ATPase, he took no precautions to avoid the use of buffers and ATP stock solutions that contained Na⁺ and K⁺. Pondering the puzzling and unreproducible results that he obtained led to the realization that contaminating salts might be influencing the reaction. When he repeated the experiments, this time avoiding contami-

nation by Na⁺ and K⁺ at all stages, he obtained clear-cut, reproducible results.

The discovery of the Na⁺/K⁺ ATPase had an enormous impact on membrane biology, leading to a better understanding of the membrane potential. The generation and disruption of membrane potential forms the basis of many biological processes, including neurotransmission and the coupling of chemical and electrical energy. For this fundamental discovery, Skou was awarded the Nobel Prize for Chemistry in 1997.

Cellular Energetics

From the growth and division of a cell to the beating of a heart to the electrical activity of a neuron that underlies thinking, life requires energy. Energy is defined as the capacity to do work, and on a cellular level that work includes conducting and regulating a multitude of chemical reactions and transport processes, growing and dividing, generating and maintaining a highly organized structure, and interacting with other cells. This chapter describes the molecular mechanisms by which cells use sunlight or chemical nutrients as sources of energy, with a special focus on how cells convert these external sources of energy into a biologically universal, intracellular, chemical energy carrier, adenosine triphosphate, or ATP (Figure 12-1). ATP, found in all types of organisms and presumably present in the earliest life-forms, is generated from the chemical addition of inorganic phosphate (HPO_4^{2-} , often abbreviated as P_i) to adenosine diphosphate, or ADP, a process called phosphorylation. Cells use the energy released during hydrolysis of the terminal phosphoanhydride bond in ATP (see Figure 2-31) to

power many otherwise energetically unfavorable processes. Examples include the synthesis of proteins from amino acids and of nucleic acids from nucleotides (Chapter 4), transport of molecules against a concentration gradient by ATP-powered pumps (Chapter 11), contraction of muscle (Chapter 17), and beating of cilia (Chapter 18). A key theme of cellular energetics is the use of proteins to use, or “couple,” energy released from one process (e.g., ATP hydrolysis) to drive another process (e.g., movement of molecules across membranes) that otherwise would be thermodynamically unfavorable.

The energy to drive ATP synthesis from ADP ($\Delta G^\circ = 7.3 \text{ kcal/mol}$) derives primarily from two sources: the energy in the chemical bonds of nutrients and the energy in sunlight (Figure 12-1). The two processes primarily responsible for converting these energy sources into ATP are **aerobic oxidation** (also known as **aerobic respiration**), which occurs in mitochondria in nearly all eukaryotic cells (Figure 12-1, *top*), and **photosynthesis**, which occurs in chloroplasts only in leaf cells of plants (Figure 12-1, *bottom*) and certain single-cell

FIGURE 12-1 Overview of aerobic oxidation and photosynthesis.

Eukaryotic cells use two fundamental mechanisms to convert external sources of energy into ATP. (*Top*) In aerobic oxidation, “fuel” molecules (primarily sugars and fatty acids) undergo preliminary processing in the cytosol, e.g., breakdown of glucose to pyruvate (**stage I**), and are then transferred into mitochondria, where they are converted by oxidation with O_2 to carbon dioxide and water (**stages II and III**) and ATP is generated (**stage IV**). (*Bottom*) In photosynthesis, which occurs in chloroplasts, the radiant energy of light is absorbed by specialized pigments (**stage 1**); the absorbed energy is used to both oxidize water

to O_2 and establish conditions (**stage 2**) necessary for the generation of ATP (**stage 3**) and carbohydrates from CO_2 (carbon fixation, **stage 4**). Both mechanisms involve the production of reduced high-energy electron carriers (NADH, NADPH, $FADH_2$) and movement of electrons down an electric potential gradient in an electron transport chain through specialized membranes. Energy from these electrons is released and captured as a proton electrochemical gradient (proton-motive force) that is then used to drive ATP synthesis. Bacteria utilize comparable processes.

organisms, such as algae and cyanobacteria. Two additional processes, glycolysis and the citric acid cycle (Figure 12-1, *top*), are also important direct or indirect sources of ATP in both animal and plant cells.

In aerobic oxidation, breakdown products of sugars (carbohydrates) and fatty acids (hydrocarbons)—both derived in animals from the digestion of food—are converted by oxidation with O_2 to carbon dioxide and water. The energy released from this overall reaction is transformed into the chemical energy of phosphoanhydride bonds in ATP. This is analogous to burning wood (carbohydrates) or oil (hydrocarbons) to generate heat in furnaces or motion in automobile engines: both consume O_2 and generate carbon dioxide and water. The key difference is that cells break the overall reaction down into many intermediate steps, with the amount of energy released in any given step closely matched to the amount of energy that can be stored—for example as ATP—or that is required for the next intermediate step. If there were not such a close match, excess released energy would be lost as heat (which would be very inefficient) or not enough energy would be released to generate energy storage molecules such as ATP or to drive the next step in the process (which would be ineffective).

In photosynthesis, the radiant energy of light is absorbed by pigments such as chlorophyll and used to make ATP and

carbohydrates—primarily sucrose and starch. Unlike aerobic oxidation, which uses carbohydrates and O_2 to generate CO_2 , photosynthesis uses CO_2 as a substrate and generates O_2 and carbohydrates as products.

This reciprocal relationship between aerobic oxidation occurring in mitochondria and photosynthesis in chloroplasts underlies a profound symbiotic relationship between photosynthetic and nonphotosynthetic organisms. The oxygen generated during photosynthesis is the source of virtually all the oxygen in the air, and the carbohydrates produced are the ultimate source of energy for virtually all nonphotosynthetic organisms on earth. (An exception is bacteria living in deep ocean vents—and the organisms that feed on them—that obtain energy for converting CO_2 into carbohydrates by oxidation of geologically generated reduced inorganic compounds released by the vents.)

At first glance, it might seem that the molecular mechanisms of photosynthesis and aerobic oxidation have little in common, besides the fact that they both produce ATP. However, a revolutionary discovery in cell biology established that bacteria, mitochondria, and chloroplasts all use the same mechanism, known as **chemiosmosis**, to generate ATP from ADP and P_i . In chemiosmosis (also known as chemiosmotic coupling), a proton electrochemical gradient is first generated across a membrane, driven by energy released as

FIGURE 12-2 The proton-motive force powers ATP synthesis.

Transmembrane proton concentration and electrical (voltage) gradients, collectively called the *proton-motive force*, are generated during aerobic oxidation and photosynthesis in eukaryotes and prokaryotes (bacteria). High-energy electrons generated by light absorption by pigments (e.g., chlorophyll), or held in the reduced form of electron carriers (e.g., NADH, FADH₂) made during the catabolism of sugars and lipids, pass down an electron transport chain (blue arrows), releasing energy throughout the process. The released energy is used to pump protons across the membrane (red arrows), generating the proton-motive force. In chemiosmotic coupling, the energy released when protons flow down the gradient through ATP synthase drives the synthesis of ATP. The proton-motive force can also power other processes, such as the transport of metabolites across the membrane against their concentration gradient and rotation of bacterial flagella.

electrons travel down their electric potential gradient through an **electron transport chain**. The energy stored in this proton electrochemical gradient, called the **proton-motive force**, is then used to power the synthesis of ATP (Figure 12-2) or other energy-requiring processes. As protons move down their electrochemical gradient through the ATP synthesis enzyme, ATP is synthesized from ADP and P_i, a process that is the reverse of the ATP-powered ion pumps discussed in the previous chapter. In this chapter, we explore the molecular mechanisms of the two processes that share this central mechanism, focusing first on aerobic oxidation and then on photosynthesis.

12.1 First Step of Harvesting Energy from Glucose: Glycolysis

In an automobile engine, hydrocarbon fuel is oxidatively and explosively converted in an essentially one-step process to mechanical work (i.e., driving a piston) plus the products CO₂

and water. The process is relatively inefficient in that substantial amounts of the chemical energy stored in the fuel are wasted as they are converted to unused heat, and substantial amounts of fuel are only partially oxidized and are released as carbonaceous, sometimes toxic, exhaust. In the competition to survive, organisms cannot afford to squander their sometimes limited energy sources on an equivalently inefficient process, and have therefore evolved a more efficient mechanism for converting fuel into work. That mechanism, known as aerobic oxidation, provides the following advantages:

- By dividing the energy conversion process into multiple steps that generate several energy-carrying intermediates, chemical bond energy is efficiently channeled into the synthesis of ATP, with less energy lost as heat.
- Different fuels (sugars and fatty acids) are reduced to common intermediates that can then share subsequent pathways for combustion and ATP synthesis.
- Because the total energy stored in the bonds of the initial fuel molecules is substantially greater than that required to drive the synthesis of a single ATP molecule (~7.3 kcal/mol), many ATP molecules are produced.

An important feature of ATP production from the breakdown of nutrient fuels into CO₂ and water (see Figure 12-1, top) is a set of reactions, called **respiration**, involving a series of oxidation and reduction reactions called an *electron transport chain*. The combination of these reactions with phosphorylation of ADP to form ATP is called **oxidative phosphorylation** and occurs in mitochondria in nearly all eukaryotic cells. When oxygen is available and used as the final recipient of the electrons transported via the electron transport chain, the respiratory process that converts nutrient energy into ATP is called *aerobic respiration* or *aerobic oxidation*. Aerobic respiration is an especially efficient way to maximize the conversion of nutrient energy into ATP because oxygen is a relatively strong oxidant. If some molecule other than oxygen, for example the weaker oxidant sulfate (SO₄²⁻) or nitrate (NO₃⁻), is the final recipient of the electrons in the electron transport chain, the process is called **anaerobic respiration**. Anaerobic respiration is typical of some prokaryotic microorganisms. Although there are exceptions, most known multicellular (metazoan) eukaryotic organisms use aerobic respiration to generate most of their ATP.

In our discussion of aerobic oxidation, we will be tracing the fate of the two main cellular fuels: sugars (principally glucose) and fatty acids. Under certain conditions amino acids also feed into these metabolic pathways. We first consider glucose oxidation, and then turn to fatty acids.

The complete aerobic oxidation of one molecule of glucose yields 6 molecules of CO₂ and the energy released is coupled to the synthesis of as many as 30 molecules of ATP. The overall reaction is

Glucose oxidation in eukaryotes takes place in four stages (see Figure 12-1, *top*):

Stage I: Glycolysis In the cytosol, one 6-carbon glucose molecule is converted by a series of reactions to two 3-carbon pyruvate molecules; a net of 2 ATPs are produced for each glucose molecule.

Stage II: Citric Acid Cycle In the mitochondrion, pyruvate oxidation to CO_2 is coupled to the generation of the high-energy electron carriers NADH and FADH_2 , which store the energy for later use.

Stage III: Electron Transport Chain High-energy electrons flow down their electric potential gradient from NADH and FADH_2 to O_2 via membrane proteins that convert the energy released into a proton-motive force (H^+ gradient).

Stage IV: ATP Synthesis The proton-motive force powers the synthesis of ATP as protons flow down their concentration and voltage gradients through the ATP synthesis enzyme. For each original glucose molecule, an estimated 28 additional ATPs are produced by this mechanism of oxidative phosphorylation.

In this section, we discuss stage I: the biochemical pathways that break down glucose into pyruvate in the cytosol. We also discuss how these pathways are regulated, and contrast the metabolism of glucose under anaerobic and aerobic conditions. The ultimate fate of pyruvate, once it enters mitochondria, is discussed in Section 12.2.

During Glycolysis (Stage I), Cytosolic Enzymes Convert Glucose to Pyruvate

Glycolysis, the first stage of glucose oxidation, occurs in the cytosol in both eukaryotes and prokaryotes; it does not require molecular oxygen (O_2), and is thus an anaerobic process. Glycolysis is an example of **catabolism**, the biological breakdown of complex substances into simpler ones. A set of 10 water-soluble cytosolic enzymes catalyze the reactions constituting the *glycolytic pathway* (*glyco*, “sweet”; *lysis*, “split”), in which one molecule of glucose is converted to two molecules of pyruvate (Figure 12-3). All the reaction intermediates produced by these enzymes are water-soluble, phosphorylated compounds called *metabolic intermediates*. In addition to chemically converting one glucose molecule into two pyruvates, the glycolytic pathway generates four ATP molecules by phosphorylation of four ADPs (reactions 7 and 10). ATP is formed directly through the enzyme-catalyzed joining of ADP and P_i that is derived from phosphorylated metabolic intermediates; this process is called **substrate-level phosphorylation** (to distinguish it from the *oxidative phosphorylation* that generates ATP in stages III and IV). Substrate-level phosphorylation in glycolysis, which does not involve the use of a proton-motive force, requires the prior addition (in reactions 1 and 3) of two phosphates

from two ATPs. These can be thought of as “pump priming” reactions, which introduce a little energy up front in order to effectively recover more energy downstream. Thus glycolysis yields a net of only two ATP molecules per glucose molecule.

The balanced chemical equation for the conversion of glucose to pyruvate shows that four hydrogen atoms (four protons and four electrons) are also released:

(For convenience, we show pyruvate here in its un-ionized form, pyruvic acid, although at physiological pH it would be largely dissociated.) All four electrons and two of the four protons are transferred (Figure 12-3, reaction 6) to two molecules of the oxidized form of **nicotinamide adenine dinucleotide** (NAD^+) to produce the reduced form of the coenzyme, NADH (see Figure 2-33):

Later we will see that the energy carried by the electrons in NADH and the analogous electron carrier FADH_2 , the reduced form of the coenzyme **flavin adenine dinucleotide** (FAD), can be used to make additional ATPs via the electron transport chain. The overall chemical equation for this first stage of glucose metabolism is

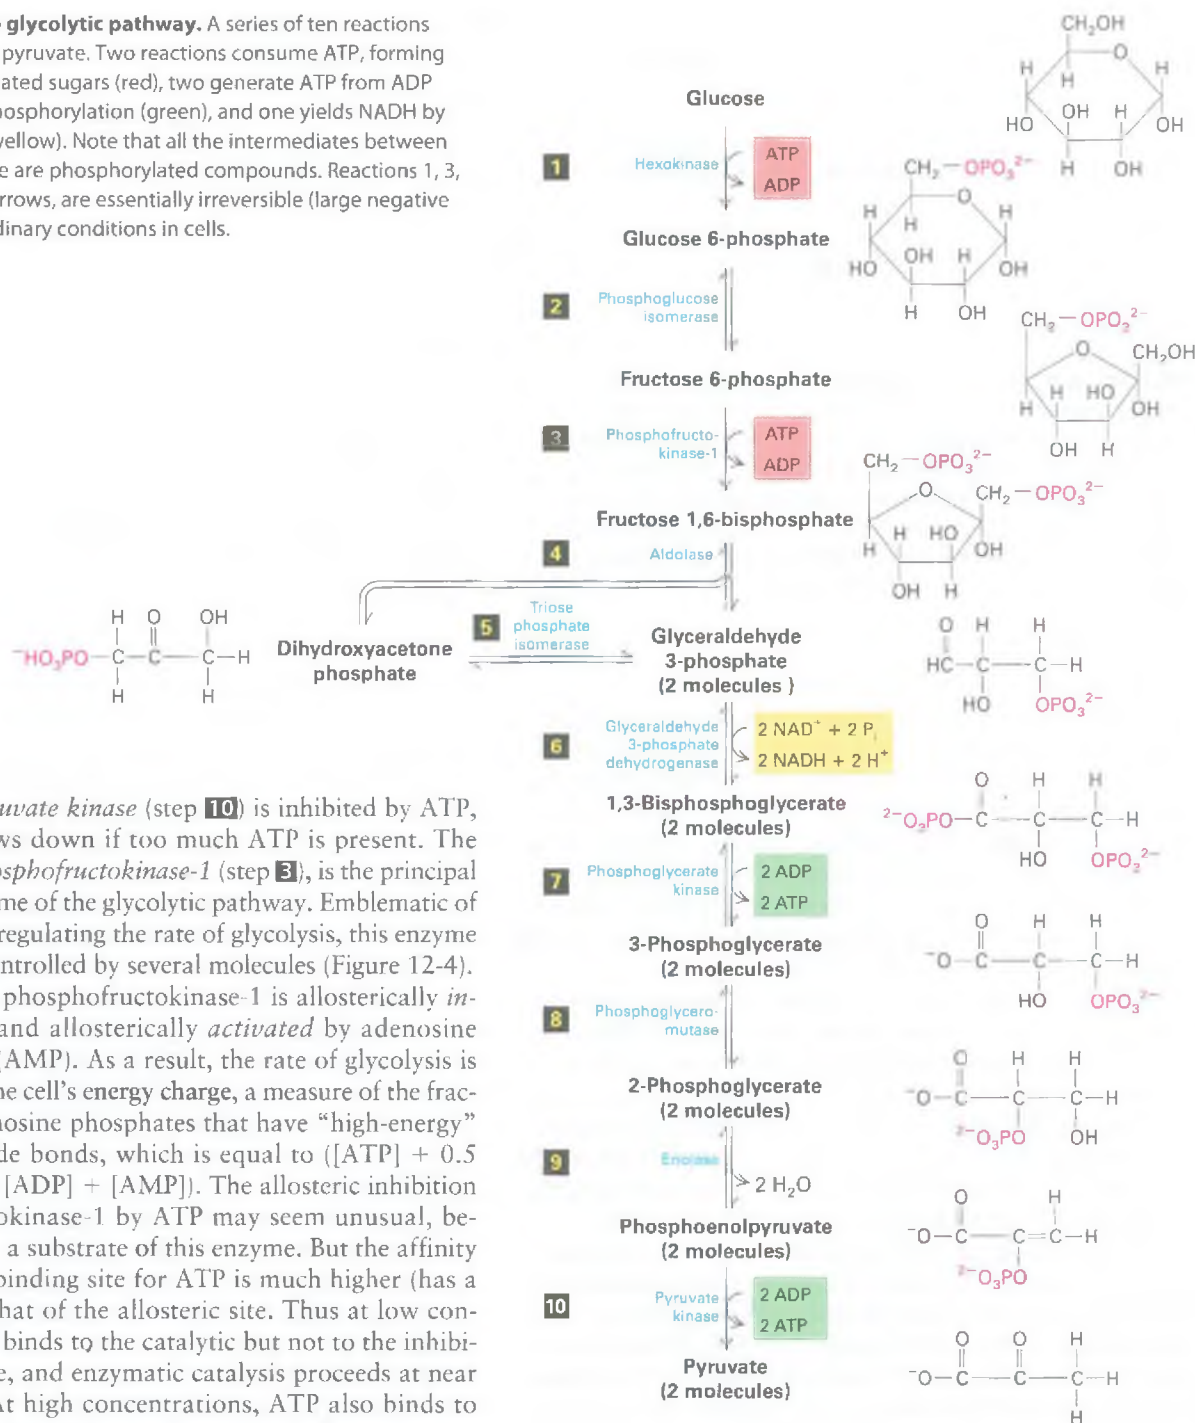

After glycolysis, only a fraction of the energy available in glucose has been extracted and converted to ATP and NADH. The rest remains trapped in the covalent bonds of the two pyruvate molecules. The ability to efficiently convert the energy remaining in pyruvate to ATP depends on the presence of molecular oxygen. As we will see, energy conversion is substantially more efficient under aerobic conditions than under anaerobic conditions.

The Rate of Glycolysis Is Adjusted to Meet the Cell's Need for ATP

To maintain appropriate levels of ATP, cells must control the rate of glucose catabolism. The operation of the glycolytic pathway (stage I), as well as the citric acid cycle (stage II), is continuously regulated, primarily by allosteric mechanisms (see Chapter 3 for general principles of allosteric control). Three allosteric enzymes involved in glycolysis play a key role in regulating the entire glycolytic pathway. *Hexokinase* (Figure 12-3, step 1) is inhibited by its reaction product, glucose

FIGURE 12-3 The glycolytic pathway. A series of ten reactions degrades glucose to pyruvate. Two reactions consume ATP, forming ADP and phosphorylated sugars (red), two generate ATP from ADP by substrate-level phosphorylation (green), and one yields NADH by reduction of NAD^+ (yellow). Note that all the intermediates between glucose and pyruvate are phosphorylated compounds. Reactions 1, 3, and 10, with single arrows, are essentially irreversible (large negative ΔG values) under ordinary conditions in cells.

6-phosphate. *Pyruvate kinase* (step **10**) is inhibited by ATP, so glycolysis slows down if too much ATP is present. The third enzyme, *phosphofructokinase-1* (step **3**), is the principal rate-limiting enzyme of the glycolytic pathway. Emblematic of its critical role in regulating the rate of glycolysis, this enzyme is allosterically controlled by several molecules (Figure 12-4).

For example, phosphofructokinase-1 is allosterically *inhibited* by ATP and allosterically *activated* by adenosine monophosphate (AMP). As a result, the rate of glycolysis is very sensitive to the cell's *energy charge*, a measure of the fraction of total adenosine phosphates that have "high-energy" phosphoanhydride bonds, which is equal to $([\text{ATP}] + 0.5 [\text{ADP}]) / ([\text{ATP}] + [\text{ADP}] + [\text{AMP}])$. The allosteric inhibition of phosphofructokinase-1 by ATP may seem unusual, because ATP is also a substrate of this enzyme. But the affinity of the substrate-binding site for ATP is much higher (has a lower K_m) than that of the allosteric site. Thus at low concentrations, ATP binds to the catalytic but not to the inhibitory allosteric site, and enzymatic catalysis proceeds at near maximal rates. At high concentrations, ATP also binds to the allosteric site, inducing a conformational change that reduces the affinity of the enzyme for the other substrate, fructose 6-phosphate, and thus reduces the rate of this reaction and the overall rate of glycolysis.

Another important allosteric activator of phosphofructokinase-1 is *fructose 2,6-bisphosphate*. This metabolite is formed from fructose 6-phosphate by an enzyme called *phosphofructokinase-2*. Fructose 6-phosphate accelerates the formation of fructose 2,6-bisphosphate, which in turn activates phosphofructokinase-1. This type of control is known as *feed-forward activation*, in which the abundance

of a metabolite (here, fructose 6-phosphate) accelerates its subsequent metabolism. Fructose 2,6-bisphosphate allosterically activates phosphofructokinase-1 in liver cells by decreasing the inhibitory effect of high ATP and by increasing the affinity of phosphofructokinase-1 for one of its substrates, fructose 6-phosphate.

The three glycolytic enzymes that are regulated by allosteric catalyze reactions with large negative ΔG° values—

FIGURE 12-4 Allosteric regulation of glucose metabolism.

The key regulatory enzyme in glycolysis, phosphofructokinase-1, is allosterically activated by AMP and fructose 2,6-bisphosphate, which are elevated when the cell's energy stores are low. The enzyme is inhibited by ATP and citrate, both of which are elevated when the cell is actively oxidizing glucose to CO_2 (i.e., when energy stores are high). Later we will see that citrate is generated during stage II of glucose oxidation. Phosphofructokinase-2 (PFK2) is a bifunctional enzyme: its

kinase activity forms fructose 2,6-bisphosphate from fructose 6-phosphate, and its phosphatase activity catalyzes the reverse reaction. Insulin, which is released by the pancreas when blood glucose levels are high, promotes PFK2 kinase activity and thus stimulates glycolysis. At low blood glucose, glucagon is released by the pancreas and promotes PFK2 phosphatase activity in the liver, indirectly slowing down glycolysis.

reactions that are essentially irreversible under ordinary conditions. These enzymes thus are particularly suitable for regulating the entire glycolytic pathway. Additional control is exerted by glyceraldehyde 3-phosphate dehydrogenase, which catalyzes the reduction of NAD^+ to NADH (see Figure 12-3, step 6). As we shall see, NADH is a high-energy electron carrier used subsequently during oxidative phosphorylation in mitochondria. If cytosolic NADH builds up owing to a slowdown in mitochondrial oxidation, step 6 becomes thermodynamically less favorable.

Glucose metabolism is controlled differently in various mammalian tissues to meet the metabolic needs of the organism as a whole. During periods of carbohydrate starvation, for instance, it is necessary for the liver to release glucose into the bloodstream. To do this, the liver converts the polymer glycogen, a storage form of glucose (Chapter 2), directly to glucose 6-phosphate (without involvement of hexokinase, step 1). Under these conditions, there is a reduction in fructose 2,6-bisphosphate levels and decreased phosphofructokinase-1 activity (Figure 12-4). As a result, glucose 6-phosphate derived from glycogen is not metabolized to pyruvate; rather, it is converted to glucose by a phosphatase and released into the blood to nourish the brain and red blood cells, which depend primarily on glucose for their energy. In all cases, the activity of these regulated enzymes is controlled by the level of small-molecule metabolites, generally by allosteric interactions, or by hormone-mediated phosphorylation and dephosphorylation reactions. (Chapter 15 gives a more detailed discussion of hormonal control of glucose metabolism in liver and muscle.)

Glucose Is Fermented When Oxygen Is Scarce

Many eukaryotes, including humans, are *obligate aerobes*: they grow only in the presence of molecular oxygen and can metabolize glucose (or related sugars) completely to CO_2 ,

with the concomitant production of a large amount of ATP. Most eukaryotes, however, can generate some ATP by anaerobic metabolism. A few eukaryotes are *facultative anaerobes*: they grow in either the presence or the absence of oxygen. For example, annelids, mollusks, and some yeasts can survive without oxygen, relying on the ATP produced by fermentation.

In the absence of oxygen, yeasts convert the pyruvate produced by glycolysis to one molecule each of ethanol and CO_2 ; in these reactions two NADH molecules are oxidized to NAD^+ for each two pyruvates converted to ethanol, thereby regenerating the supply of NAD^+ , which is necessary for glycolysis to continue (Figure 12-5a, left). This anaerobic catabolism of glucose, called **fermentation**, is the basis of beer and wine production.

Fermentation also occurs in animal cells, although lactic acid rather than alcohol is the product. During prolonged contraction of mammalian skeletal muscle cells—for example, during exercise—oxygen within the muscle tissue can become scarce. As a consequence, glucose catabolism is limited to glycolysis and muscle cells convert pyruvate to two molecules of lactic acid by a reduction reaction that also oxidizes two NADHs to two NAD^+ s (Figure 12-5a, right). Although the lactic acid is released from the muscle into the blood, if the contractions are sufficiently rapid and strong, the lactic acid can transiently accumulate in the tissue and contribute to muscle and joint pain during exercise. Once it is secreted into the blood, some of the lactic acid passes into the liver, where it is reoxidized to pyruvate and either further metabolized to CO_2 aerobically or converted back to glucose. Much lactate is metabolized to CO_2 by the heart, which is highly perfused by blood and can continue aerobic metabolism at times when exercising, oxygen-poor skeletal muscles secrete lactate. Lactic acid bacteria (the organisms that spoil milk) and other prokaryotes also generate ATP by the fermentation of glucose to lactic acid.

(b)

AEROBIC METABOLISM

Overall reaction of aerobic metabolism:

**FIGURE 12-5 Anaerobic versus aerobic metabolism of glucose.**

The ultimate fate of pyruvate formed during glycolysis depends on the presence or absence of oxygen. (a) In the absence of oxygen, pyruvate is only partially degraded and no further ATP is made. However, two electrons are transferred from each NADH molecule produced during glycolysis to an acceptor molecule to regenerate NAD^+ , which is required for continued glycolysis. In yeast (left), acetaldehyde is the electron acceptor and ethanol is the product. This process is called *alcoholic fermentation*. When oxygen is scarce in muscle cells (right),

NADH reduces pyruvate to form lactic acid, regenerating NAD^+ , a process called *lactic acid fermentation*. (b) In the presence of oxygen, pyruvate is transported into mitochondria, where first it is converted by pyruvate dehydrogenase into one molecule of CO_2 and one of acetic acid, the latter linked to coenzyme A (CoA-SH) to form acetyl CoA, concomitant with reduction of one molecule of NAD^+ to NADH. Further metabolism of acetyl CoA and NADH generates approximately an additional 28 molecules of ATP per glucose molecule oxidized.

Fermentation is a much less efficient way to generate ATP than aerobic oxidation, and therefore in animal cells only occurs when oxygen is scarce. In the presence of oxygen, pyruvate formed by glycolysis is transported into mitochondria, where it is oxidized by O_2 to CO_2 and H_2O via the series of reactions outlined in Figure 12-5b. This aerobic metabolism of glucose, which occurs in stages II–IV of the process outlined in Figure 12-1, generates an estimated 28 additional ATP molecules per original glucose molecule, far outstripping the ATP yield from anaerobic glucose metabolism (fermentation).

To understand how ATP is generated so efficiently by aerobic oxidation, we must consider first the structure and function of the organelle responsible, the mitochondrion. Mitochondria, and the reactions that take place within them, are the subjects of the next section.

KEY CONCEPTS of Section 12.1

First Step of Harvesting Energy from Glucose: Glycolysis

- In a process known as aerobic oxidation, cells convert the energy released by the oxidation (“burning”) of glucose or fatty acids into the terminal phosphoanhydride bond of ATP.
- The complete aerobic oxidation of each molecule of glucose produces six molecules of CO_2 and approximately 30 ATP molecules. The entire process, which starts in the cytosol and is completed in the mitochondrion, can be divided into four stages: (I) degradation of glucose to pyruvate in the cytosol (glycolysis); (II) pyruvate oxidation to CO_2 in the mitochondrion coupled to generation of the high-energy electron carriers NADH and $FADH_2$ (via the citric acid cycle); (III) electron transport to generate a proton-motive force together with conversion of molecular oxygen to water; and (IV) ATP synthesis (see Figure 12-1). From each glucose molecule two ATPs are generated by glycolysis (stage I) and approximately 28 from stages II–IV.
- In glycolysis (stage I), cytosolic enzymes convert glucose to two molecules of pyruvate and generate two molecules each of NADH and ATP (see Figure 12-3).
- The rate of glucose oxidation via glycolysis is regulated by the inhibition or stimulation of several enzymes, depending on the cell’s need for ATP. Glucose is stored (as glycogen or fat) when ATP is abundant (see Figure 12-4).
- In the absence of oxygen (anaerobic conditions), cells can metabolize pyruvate to lactic acid or (in the case of yeast) to ethanol and CO_2 , in the process converting NADH back to NAD^+ , which is necessary for continued glycolysis. In the presence of oxygen (aerobic conditions), pyruvate is transported into the mitochondrion, where it is metabolized to CO_2 , in the process generating abundant ATP (see Figure 12-5).

12.2 Mitochondria and the Citric Acid Cycle

Oxygen-producing photosynthetic cyanobacteria appeared about 2.7 billion years ago. The subsequent buildup in the earth’s atmosphere of sufficient oxygen (O_2) during the next approximately billion years opened the way for organisms to evolve the very efficient aerobic oxidation pathway, which in turn permitted the evolution, especially during what is called the Cambrian explosion, of large and complex body forms and associated metabolic activities. In eukaryotic cells, aerobic oxidation is carried out by mitochondria (stages II–IV). In effect, mitochondria are ATP-generating factories, taking full advantage of this plentiful oxygen. We first describe their structure and then the reactions they employ to degrade pyruvate and make ATP.

Mitochondria Are Dynamic Organelles with Two Structurally and Functionally Distinct Membranes

Mitochondria (Figure 12-6) are among the larger organelles in the cell. A mitochondrion is about the size of an *E. coli* bacterium, which is not surprising, because bacteria are thought to be the evolutionary precursors of mitochondria (see discussion of the endosymbiont hypothesis, below). Most eukaryotic cells contain many mitochondria, which may collectively occupy as much as 25 percent of the volume of the cytoplasm. The numbers of mitochondria in a cell, hundreds to thousands in mammalian cells, are regulated to match the cell’s requirements for ATP (e.g., stomach cells, which use a lot of ATP for acid secretion, have many mitochondria).

The details of mitochondrial structure can be observed with electron microscopy (see Figure 9-33). Each mitochondrion has two distinct, concentric membranes: the inner and outer membrane. The outer membrane defines the smooth outer perimeter of the mitochondrion. The inner membrane lies immediately underneath the outer membrane and has numerous invaginations, called *cristae*, which extend from the perimeter of the inner membrane into the center of the mitochondrion. The high membrane curvature at the tips of the cristae may be due to the presence of a high concentration of dimers of an integral membrane protein that synthesizes ATP (the F_0F_1 complex, discussed in Section 12.3). The outer and inner membranes topologically define two submitochondrial compartments: the *intermembrane space*, between the outer and inner membranes, and the *matrix*, or central compartment, which forms the lumen within the inner membrane. The invaginating cristae greatly expand the surface area of the inner mitochondrial membrane, thus increasing the ability to synthesize ATP. In typical liver mitochondria, for example, the area of the inner membrane, including cristae, is about five times that of the outer membrane. In fact, the total area of all inner mitochondrial membranes in liver cells is about 17 times that of the plasma

FIGURE 12-6 Internal structure of a mitochondrion. (a) Schematic diagram showing the principal membranes and compartments. The smooth outer membrane forms the outside boundary of the mitochondrion. The inner membrane is distinct from the outer membrane and is highly invaginated to form sheets and tubes called cristae. The relatively small uniform tubular structures that connect the cristae to the portions of the inner membrane that are juxtaposed to the outer membrane are called *crista junctions*. The intermembrane space is continuous with the lumen of each crista. The F_0F_1 complexes (small red spheres), which synthesize ATP, are intramembrane particles that protrude from the cristae and inner membrane into the matrix. The matrix

contains the mitochondrial DNA (blue strand), ribosomes (small blue spheres), and granules (large yellow spheres). (b) Computer-generated model of a section of a mitochondrion from chicken brain. This model is based on a three-dimensional electron microscopic image calculated from a series of two-dimensional electron micrographs recorded at regular intervals. This technique is analogous to a three-dimensional x-ray tomogram or CAT scan used in medical imaging. Note the tightly packed cristae (yellow-green), the inner membrane (light blue), and the outer membrane (dark blue). [Part (b) courtesy of T. Frey, from T. Frey and C. Mannella, 2000, *Trends Biochem. Sci.* **25**:319.]

membrane. The mitochondria in heart and skeletal muscles contain three times as many cristae as are found in typical liver mitochondria—presumably reflecting the greater demand for ATP by muscle cells.

Analysis of fluorescently labeled mitochondria in living cells has shown that mitochondria are highly dynamic. They undergo frequent fusions and fissions that generate tubular, sometimes branched networks (Figure 12-7), which may account for the wide variety of mitochondrial morphologies seen in different types of cells. When individual mitochondria fuse, each of the two membranes fuse (inner with inner, and outer with outer) and each of their distinct compartments intermix (matrix with matrix, intermembrane space with intermembrane space). Fusions and fissions apparently play a functional role as well, because genetic disruptions in several GTPase superfamily genes that are required for these dynamic processes can disrupt mitochondrial function, such as maintenance of proper inner membrane electric potential,

and cause human disease. An example is the inherited neuromuscular disease Charcot-Marie-Tooth subtype 2A, in which defects in peripheral nerve function lead to progressive muscle weakness, mainly in the feet and hands. The ongoing fusion and fission process appears to protect mitochondrial DNA from accumulating mutations, and may permit the isolation of dysfunctional or damaged segments of mitochondria that can be specifically targeted for destruction in the cell by a process called autophagy (see Chapter 14).

Fractionation and purification of mitochondrial membranes and compartments have made it possible to determine their protein, DNA, and phospholipid compositions and to localize each enzyme-catalyzed reaction to a specific membrane or compartment. Over 1000 different types of polypeptides are required to make and maintain mitochondria and permit them to function. Detailed biochemical analysis has established that there are at least 1098 proteins in mammalian mitochondria and perhaps as many as 1500. Only a small number of these—

VIDEO: Mitochondrial Fusion and Fission

Mitochondria labeled with a fluorescent protein in a living normal murine embryonic fibroblast were observed using time-lapse fluorescence microscopy. Several mitochondria undergoing fusion (top) or fission (bottom) are artificially highlighted in blue and with arrows. [Modified from D. C. Chan, 2006, *Cell* 125(7):1241–1252.]

13 in humans—are encoded by mitochondrial DNA genes and synthesized inside the mitochondrial matrix space. The remaining proteins are encoded by nuclear genes (Chapter 6), synthesized in the cytosol, and then imported into mitochondria (Chapter 13). Defective functioning of the mitochondrial-associated proteins, due for example to inherited genetic mutations, leads to over 150 human diseases. The most common of these are electron transport chain diseases, which result from mutations in any one of 92 protein-encoding genes and exhibit a very wide variety of clinical abnormalities affecting muscles, the heart, the nervous system, and the liver, among other physiologic systems. Other mitochondrial-associated diseases include Miller syndrome, which results in multiple anatomical malformations, and connective tissue defects.

The most abundant protein in the outer membrane is mitochondrial **porin**, a transmembrane channel protein similar in structure to bacterial porins (see Figure 10-18). Ions and most small molecules (up to about 5000 Da) can readily pass through these channel proteins when they are open. Although there may be metabolic regulation of the opening of mitochondrial porins and thus the flow of metabolites across the outer membrane, the inner membrane and its cristae are the major permeability barriers between the cytosol and the mitochondrial matrix, limiting the rate of mitochondrial oxidation and ATP generation.

Protein constitutes 76 percent of the total mass of the inner mitochondrial membrane—a higher fraction than in any other cellular membrane. Many of these proteins are key participants in oxidative phosphorylation. They include ATP synthase, proteins responsible for electron transport, and a wide variety of transport proteins that permit the movement of metabolites between the cytosol and the mitochondrial matrix. The human genome encodes 48 members of a family of mitochondrial transport proteins. One of these is called the ADP/ATP carrier, an antiporter that moves newly synthesized ATP out of the matrix and into the inner membrane space (and subsequently the cytosol) in exchange for ADP originating from the cytosol. Without this essential antiporter, the energy trapped in the chemical bonds in mitochondrial ATP would not be available to the rest of the cell.

Note that plants have mitochondria and perform aerobic oxidation as well. In plants, stored carbohydrates, mostly in the form of starch, are hydrolyzed to glucose. Glycolysis then produces pyruvate that is transported into mitochondria, as in animal cells. Mitochondrial oxidation of pyruvate and concomitant formation of ATP occur in photosynthetic cells during dark periods when photosynthesis is not possible, and in roots and other nonphotosynthetic tissues at all times.

The mitochondrial inner membrane, cristae, and matrix are the sites of most reactions involving the oxidation of pyruvate and fatty acids to CO_2 and H_2O and the coupled synthesis of ATP from ADP and P_i , with each reaction occurring in a discrete membrane or space in the mitochondrion (Figure 12-8).

We now continue our detailed discussion of glucose oxidation and ATP generation, exploring what happens to the pyruvate generated during glycolysis (stage I) after it is transported into the mitochondrial matrix. The last three of the four stages of glucose oxidation are:

- **Stage II.** Stage II can be subdivided into two distinct parts: (1) the conversion of pyruvate to acetyl CoA, followed by (2) oxidation of acetyl CoA to CO_2 in the citric acid cycle. These oxidations are coupled to reduction of NAD^+ to NADH and of FAD to FADH_2 . (Fatty acid oxidation follows a similar route, with conversion of fatty acyl CoA to acetyl CoA.) Most of the reactions occur in or on the membrane facing the matrix.
- **Stage III.** Electron transfer from NADH and FADH_2 to O_2 via an electron transport chain within the inner membrane, which generates a proton-motive force across that membrane.
- **Stage IV.** Harnessing the energy of the proton-motive force for ATP synthesis in the mitochondrial inner membrane. Stages III and IV are together called oxidative phosphorylation.

In the First Part of Stage II, Pyruvate Is Converted to Acetyl CoA and High-Energy Electrons

Within the mitochondrial matrix, pyruvate reacts with coenzyme A, forming CO_2 , acetyl CoA, and NADH (Figure 12-8, Stage II left). This reaction, catalyzed by *pyruvate*

FIGURE 12-8 Summary of aerobic oxidation of glucose and fatty acids. **Stage I:** In the cytosol, glucose is converted to pyruvate (glycolysis) and fatty acid to fatty acyl CoA. Pyruvate and fatty acyl CoA then move into the mitochondrion. Mitochondrial porins make the outer membrane permeable to these metabolites, but specific transport proteins (colored ovals) in the inner membrane are required to import pyruvate (yellow) and fatty acids (blue) into the matrix. Fatty acyl groups are transferred from fatty acyl CoA to an intermediate carrier, transported across the inner membrane (blue oval), and then reattached to CoA on the matrix side. **Stage II:** In the mitochondrial matrix, pyruvate and fatty acyl CoA are converted to acetyl CoA and then oxidized, releasing CO₂. Pyruvate is converted to acetyl CoA with the formation of NADH and CO₂; two carbons from fatty acyl CoA are converted to acetyl CoA with the formation of FADH₂ and NADH. Oxidation of acetyl CoA in the citric acid cycle generates NADH and FADH₂, GTP,

and CO₂. **Stage III:** Electron transport reduces oxygen to water and generates a proton-motive force. Electrons (blue) from reduced coenzymes are transferred via electron-transport complexes (blue boxes) to O₂ concomitant with transport of H⁺ ions (red) from the matrix to the intermembrane space, generating the proton-motive force. Electrons from NADH flow directly from complex I to complex III, bypassing complex II. Electrons from FADH₂ flow directly from complex II to complex III, bypassing complex I. **Stage IV:** ATP synthase, the F₀F₁ complex (orange), harnesses the proton-motive force to synthesize ATP in the matrix. Antiporter proteins (purple and green ovals) transport ADP and P_i into the matrix and export hydroxyl groups and ATP. NADH generated in the cytosol is not transported directly to the matrix because the inner membrane is impermeable to NAD⁺ and NADH; instead, a shuttle system (red) transports electrons from cytosolic NADH to NAD⁺ in the matrix. O₂ diffuses into the matrix, and CO₂ diffuses out.

dehydrogenase, is highly exergonic ($\Delta G^{\circ} = -8.0$ kcal/mol) and essentially irreversible.

Acetyl CoA is a molecule consisting of a two-carbon acetyl group covalently linked to a longer molecule known as coenzyme A (CoA) (Figure 12-9). It plays a central role in the oxidation of pyruvate, fatty acids, and amino acids. In addition, it is an intermediate in numerous biosynthetic reactions, including transfer of an acetyl group to histone proteins and many mammalian proteins, and synthesis of lipids such as cholesterol. In respiring mitochondria, however, the two-carbon acetyl group of acetyl CoA is almost always

oxidized to CO₂ via the citric acid cycle. Note that the two carbons in the acetyl group come from pyruvate; the third carbon of pyruvate is released as carbon dioxide.

In the Second Part of Stage II, the Citric Acid Cycle Oxidizes the Acetyl Group in Acetyl CoA to CO₂ and Generates High-Energy Electrons

Nine sequential reactions operate in a cycle to oxidize the acetyl group of acetyl CoA to CO₂ (Figure 12-8, Stage II right). The cycle is referred to by several names: the citric acid cycle,

FIGURE 12-9 The structure of acetyl CoA. This compound, consisting of an acetyl group covalently linked to a coenzyme A (CoA) molecule, is an important intermediate in the aerobic oxidation of

pyruvate, fatty acids, and many amino acids. It also contributes acetyl groups in many biosynthetic pathways.

the tricarboxylic acid (TCA) cycle, and the Krebs cycle. The net result is that for each acetyl group entering the cycle as acetyl CoA, two molecules of CO_2 , three of NADH, and one each of FADH_2 and GTP are produced. NADH and FADH_2 are high-energy electron carriers that will play a major role in stage III of mitochondrial oxidation: electron transport.

As shown in Figure 12-10, the cycle begins with condensation of the two-carbon acetyl group from acetyl CoA with the four-carbon molecule *oxaloacetate* to yield the six-carbon *citric acid* (hence the name citric acid cycle). In both reactions 4 and 5, a CO_2 molecule is released and NAD^+ is reduced to NADH. Reduction of NAD^+ to NADH also occurs during

reaction 9; thus three NADHs are generated per turn of the cycle. In reaction 7, two electrons and two protons are transferred to FAD, yielding the reduced form of this coenzyme, FADH_2 . Reaction 7 is distinctive because not only is it an intrinsic part of the citric acid cycle (stage II), but it is also catalyzed by a membrane-attached enzyme that, as we shall see, also plays an important role in stage III. In reaction 6, hydrolysis of the high-energy thioester bond in succinyl CoA is coupled to synthesis of one GTP by substrate-level phosphorylation. Because GTP and ATP are interconvertible,

FIGURE 12-10 The citric acid cycle. Acetyl CoA is metabolized to CO_2 and the high-energy electron carriers NADH and FADH_2 . In reaction 1, a two-carbon acetyl residue from acetyl CoA condenses with the four-carbon molecule oxaloacetate to form the six-carbon citrate. In the remaining reactions (2–9) each molecule of citrate is eventually converted back to oxaloacetate, losing two CO_2 molecules in the process. In each turn of the cycle, four pairs of electrons are removed from carbon atoms, forming three molecules of NADH, one molecule of

FADH_2 and one molecule of GTP. The two carbon atoms that enter the cycle with acetyl CoA are highlighted in blue through succinyl CoA. In succinate and fumarate, which are symmetric molecules, they can no longer be specifically denoted. Isotope-labeling studies have shown that these carbon atoms are *not* lost in the turn of the cycle in which they enter; on average, one will be lost as CO_2 during the next turn of the cycle and the other in subsequent turns.

TABLE 12-1 Net Result of the Glycolytic Pathway and the Citric Acid Cycle

Reaction	CO ₂ Molecules Produced	NAD ⁺ Molecules Reduced to NADH	FAD Molecules Reduced to FADH ₂	ATP (OR GTP)
1 glucose molecule to 2 pyruvate molecules	0	2	0	2
2 pyruvates to 2 acetyl CoA molecules	2	2	0	0
2 acetyl CoA to 4 CO ₂ molecules	4	6	2	2
Total	6	10	2	4

this can be considered an ATP-generating step. Reaction 9 regenerates oxaloacetate, so the cycle can begin again. Note that molecular O₂ does not participate in the citric acid cycle.

Most enzymes and small molecules involved in the citric acid cycle are soluble in the aqueous mitochondrial matrix. These include CoA, acetyl CoA, succinyl CoA, NAD⁺, and NADH, as well as most of the eight cycle enzymes. *Succinate dehydrogenase* (reaction 7), however, is a component of an integral membrane protein in the inner membrane, with its active site facing the matrix. When mitochondria are disrupted by gentle ultrasonic vibration or by osmotic lysis, non-membrane-bound enzymes in the citric acid cycle are released as very large multiprotein complexes. It is believed that, within such complexes, the reaction product of one enzyme passes directly to the next enzyme without diffusing through the solution. Much work is needed to determine the structures of these large enzyme complexes as they exist in the cell.

Because glycolysis of one glucose molecule generates two acetyl CoA molecules, the reactions in the glycolytic pathway and citric acid cycle produce six CO₂ molecules, 10 NADH molecules, and two FADH₂ molecules per glucose molecule (Table 12-1). Although these reactions also generate four high-energy phosphoanhydride bonds in the form of two ATP and two GTP molecules, this represents only a small fraction of the available energy released in the complete aerobic oxidation of glucose. The remaining energy is stored as high-energy electrons in the reduced coenzymes NADH and FADH₂, which can be thought of as “electron carriers.” The goal of stages III and IV is to recover this energy in the form of ATP.

Transporters in the Inner Mitochondrial Membrane Help Maintain Appropriate Cytosolic and Matrix Concentrations of NAD⁺ and NADH

In the cytosol NAD⁺ is required for step 6 of glycolysis (see Figure 12-3), and in the mitochondrial matrix NAD⁺ is required for conversion of pyruvate to acetyl CoA and for three steps in the citric acid cycle (4, 5, and 9 in Figure 12-10). In each case, NADH is a product of the reaction. If glycolysis and oxidation of pyruvate are to continue, NAD⁺ must be regenerated by oxidation of NADH. (Similarly, the FADH₂ generated in stage II reactions must be reoxidized to FAD if

FAD-dependent reactions are to continue.) As we will see in the next section, the electron transport chain *within* the mitochondrial inner membrane converts NADH to NAD⁺ and FADH₂ to FAD as it reduces O₂ to water and converts the energy stored in the high-energy electrons in the reduced forms of these molecules into a proton-motive force (stage III). Even though O₂ is not involved in any reaction of the citric acid cycle, in the absence of O₂ this cycle soon stops operating as the intramitochondrial supplies of NAD⁺ and FAD dwindle due to the inability of the electron transport chain to oxidize NADH and FADH₂. These observations raise the question of how a supply of NAD⁺ in the cytosol is regenerated.

If the NADH from the cytosol could move into the mitochondrial matrix and be oxidized by the electron transport chain and if the NAD⁺ product could be transported back into the cytosol, regeneration of cytosolic NAD⁺ would be simple. However, the inner mitochondrial membrane is impermeable to NADH. To bypass this problem and permit the electrons from cytosolic NADH to be transferred *indirectly* to O₂ via the mitochondrial electron transport chain, cells use several *electron shuttles* to transfer electrons from cytosolic NADH to NAD⁺ in the matrix. Operation of the most widespread shuttle—the *malate-aspartate shuttle*—is depicted in Figure 12-11.

For every complete “turn” of the cycle, there is no overall change in the numbers of NADH and NAD⁺ molecules or the intermediates aspartate or malate used by the shuttle. However, in the cytosol, NADH is oxidized to NAD⁺, which can be used for glycolysis, and in the matrix, NAD⁺ is reduced to NADH, which can be used for electron transport:

Mitochondrial Oxidation of Fatty Acids Generates ATP

Up to now, we have focused mainly on the oxidation of carbohydrates, namely glucose, for ATP generation. Fatty acids are another important source of cellular energy. Cells can take up either glucose or fatty acids from the extracellular space with the help of specific transporter proteins (Chapter 11). Should a cell not need to immediately burn these molecules, it

FIGURE 12-11 The malate-aspartate shuttle. This cyclical series of reactions transfers electrons from NADH in the cytosol (intermembrane space) across the inner mitochondrial membrane, which is impermeable to NADH itself, to NAD⁺ in the matrix. The net result is the replacement of cytosolic NADH with NAD⁺ and matrix NAD⁺ with NADH. Step **1**: Cytosolic malate dehydrogenase transfers electrons from cytosolic NADH to oxaloacetate, forming malate. Step **2**: An antiporter (blue oval) in the inner mitochondrial membrane transports malate into the matrix in exchange for α-ketoglutarate. Step **3**: Mitochondrial malate dehydrogenase converts malate back to oxaloacetate, reducing NAD⁺ in the matrix to NADH in the process. Step **4**: Oxaloacetate, which

cannot directly cross the inner membrane, is converted to aspartate by addition of an amino group from glutamate. In this transaminase-catalyzed reaction in the matrix, glutamate is converted to α-ketoglutarate. Step **5**: A second antiporter (red oval) exports aspartate to the cytosol in exchange for glutamate. Step **6**: A cytosolic transaminase converts aspartate to oxaloacetate and α-ketoglutarate to glutamate, completing the cycle. The blue arrows reflect the movement of the α-ketoglutarate, the red arrows the movement of glutamate, and the black arrows that of aspartate/malate. It is noteworthy that, as aspartate and malate cycle clockwise, glutamate and α-ketoglutarate cycle in the opposite direction.

can store them as a polymer of glucose called glycogen (especially in muscle or liver) or as a trimer of fatty acids covalently linked to glycerol, called a **triacylglycerol** or **triglyceride**. In some cells, excess glucose is converted into fatty acids and then triacylglycerols for storage. However, unlike microorganisms, animals are unable to convert fatty acids to glucose. When the cells need to burn these energy stores to make ATP (e.g., when a resting muscle begins to do work and needs to burn glucose or fatty acids as fuel), enzymes break down glycogen to glucose or hydrolyze triacylglycerols to fatty acids, which are then oxidized to generate ATP:

of glucose. The oxidation of 1 g of triacylglyceride to CO₂ generates about six times as much ATP as does the oxidation of 1 g of hydrated glycogen. Thus triglycerides are more efficient than carbohydrates for storage of energy, in part because they are stored in anhydrous form and can yield more energy when oxidized and in part because they are intrinsically more reduced (have more hydrogens) than carbohydrates. In mammals, the primary site of storage of triacylglycerides is fat (adipose) tissue, whereas the primary sites for glycogen storage are muscle and the liver.

Just as there are four stages in the oxidation of glucose, there are four stages in the oxidation of fatty acids. To optimize the efficiency of ATP generation, part of stage II (citric acid cycle oxidation of acetyl CoA) and all of stages III and IV of fatty acid oxidation are identical to those of glucose oxidation. The differences lie in the cytosolic stage I and the first part of the mitochondrial stage II. In stage I, fatty acids are converted to a fatty acyl CoA in the cytosol in a reaction coupled to the hydrolysis of ATP to AMP and PP_i (inorganic pyrophosphate) (see Figure 12-8):

Fatty acids are the major energy source for some tissues, particularly adult heart muscle. In humans, in fact, more ATP is generated by the oxidation of fats than the oxidation

Subsequent hydrolysis of PP_i to two molecules of P_i releases energy that drives this reaction to completion. To transfer the fatty acyl group into the mitochondrial matrix, it is covalently transferred to a molecule called carnitine and moved across the inner mitochondrial membrane by an acylcarnitine transporter protein (see Figure 12-8, blue oval); then, on the matrix side, the fatty acyl group is released from carnitine and reattached to another CoA molecule. The activity of the acylcarnitine transporter is regulated to prevent oxidation of fatty acids when cells have adequate energy (ATP) supplies.

In the first part of stage II, each molecule of a fatty acyl CoA in the mitochondrion is oxidized in a cyclical sequence of four reactions in which all the carbon atoms are converted two at a time to acetyl CoA with generation of FADH_2 and NADH (Figure 12-12a). For example, mitochondrial oxidation of each molecule of the 18-carbon stearic acid, $\text{CH}_3(\text{CH}_2)_{16}\text{COOH}$, yields nine molecules of acetyl CoA and eight molecules each of NADH and FADH_2 . In the second part of stage II, as with acetyl CoA generated from pyruvate, these acetyl groups

enter the citric acid cycle and are oxidized to CO_2 . As will be described in detail in the next section, the reduced NADH and FADH_2 with their high-energy electrons will be used in stage III to generate a proton-motive force that in turn is used in stage IV to power ATP synthesis.

Peroxisomal Oxidation of Fatty Acids Generates No ATP

Mitochondrial oxidation of fatty acids is the major source of ATP in mammalian liver cells, and biochemists at one time believed this was true in all cell types. However, rats treated with clofibrate, a drug that affects many features of lipid metabolism, were found to exhibit an increased rate of fatty acid oxidation and a large increase in the number of peroxisomes in their liver cells. This finding suggested that peroxisomes, as well as mitochondria, can oxidize fatty acids. These small organelles, $\sim 0.2\text{--}1\text{ }\mu\text{m}$ in diameter, are lined by a single membrane (see Figure 9-32). They are present in all

(a) MITOCHONDRIAL OXIDATION (b) PEROXISOMAL OXIDATION

FIGURE 12-12 Oxidation of fatty acids in mitochondria and peroxisomes. In both mitochondrial oxidation (a) and peroxisomal oxidation (b), fatty acids are converted to acetyl CoA by a series of four enzyme-catalyzed reactions (shown down the center of the figure). A fatty acyl CoA molecule is converted to acetyl CoA and a fatty acyl CoA shortened by two carbon atoms. Concomitantly, one FAD molecule is reduced to FADH_2 and one NAD^+ molecule is reduced to NADH . The cycle is repeated on the shortened acyl CoA until fatty acids with an even number of carbon atoms are completely converted to acetyl CoA. In mitochondria, electrons from FADH_2 and NADH enter the electron transport chain and ultimately are used to generate ATP; the acetyl CoA generated is oxidized in the citric acid cycle, resulting in release of CO_2 and ultimately the synthesis of additional ATP. Because peroxisomes lack the electron transport complexes composing the electron transport chain and the enzymes of the citric acid cycle, oxidation of fatty acids in these organelles yields no ATP.

[Adapted from D. L. Nelson and M. M. Cox, *Lehninger Principles of Biochemistry*, 3d ed., 2000, Worth Publishers.]

mammalian cells except erythrocytes and are also found in plant cells, yeasts, and probably most other eukaryotic cells.

Mitochondria preferentially oxidize short-chain (fewer than 8 carbons in the fatty acyl chain, or $<C_8$), medium-chain (C_8 – C_{12}), and long-chain (C_{14} – C_{20}) fatty acids, whereas peroxisomes preferentially oxidize very long-chain fatty acids (VLCFAs, $>C_{20}$), which cannot be oxidized by mitochondria. Most dietary fatty acids have long chains, which means they are oxidized mostly in mitochondria. In contrast to mitochondrial oxidation of fatty acids, which is coupled to generation of ATP, peroxisomal oxidation of fatty acids is not linked to ATP formation, and energy is released as heat.

The reaction pathway by which fatty acids are degraded to acetyl CoA in peroxisomes is similar to that used in mitochondria (Figure 12-12b). However, peroxisomes lack an electron transport chain, and electrons from the $FADH_2$ produced during the oxidation of fatty acids are immediately transferred to O_2 by *oxidases*, regenerating FAD and forming hydrogen peroxide (H_2O_2). In addition to oxidases, peroxisomes contain abundant *catalase*, which quickly decomposes the H_2O_2 , a highly cytotoxic metabolite. NADH produced during oxidation of fatty acids is exported and reoxidized in the cytosol; there is no need for a malate-aspartate shuttle here. Peroxisomes also lack the citric acid cycle, so acetyl CoA generated during peroxisomal degradation of fatty acids cannot be oxidized further; instead it is transported into the cytosol for use in the synthesis of cholesterol (Chapter 10) and other metabolites.

KEY CONCEPTS of Section 12.2

Mitochondria and the Citric Acid Cycle

- The mitochondrion has two distinct membranes (outer and inner) and two distinct subcompartments (intermembrane space between the two membranes, and the matrix surrounded by the inner membrane). Aerobic oxidation occurs in the mitochondrial matrix and on the inner mitochondrial membrane (see Figure 12-6).
- In stage II of glucose oxidation, the three-carbon pyruvate molecule is first oxidized to generate one molecule each of CO_2 , NADH, and acetyl CoA. The acetyl group of acetyl CoA is then oxidized to CO_2 by the citric acid cycle (see Figure 12-8).
- Each turn of the citric acid cycle releases two molecules of CO_2 and generates three NADH molecules, one $FADH_2$ molecule, and one GTP (see Figure 12-10).
- Most of the energy released in stages I and II of glucose oxidation is temporarily stored in the reduced coenzymes NADH or $FADH_2$, which carry high-energy electrons that subsequently drive the electron transport chain (stage III).
- Neither glycolysis nor the citric acid cycle directly use molecular oxygen (O_2).
- The malate-aspartate shuttle regenerates the supply of cytosolic NAD^+ necessary for continued glycolysis (see Figure 12-11).

- Like glucose oxidation, the oxidation of fatty acids takes place in four stages. In stage I, fatty acids are converted to fatty acyl CoA in the cytosol. In stage II, the fatty acyl CoA is first converted into multiple acetyl CoA molecules with generation of NADH and $FADH_2$. Then, as in glucose oxidation, the acetyl CoA enters the citric acid cycle. Stages III and IV are identical for fatty acid and glucose oxidation (see Figure 12-8).

- In most eukaryotic cells, oxidation of short- to long-chain fatty acids occurs in mitochondria with production of ATP, whereas oxidation of very long-chain fatty acids occurs primarily in peroxisomes and is not linked to ATP production (see Figure 12-12); the energy released during peroxisomal oxidation of fatty acids is converted to heat.

12.3 The Electron Transport Chain and Generation of the Proton-Motive Force

Most of the energy released during the oxidation of glucose and fatty acids to CO_2 (stages I and II) is converted into high-energy electrons in the reduced coenzymes NADH and $FADH_2$. We now turn to stage III, in which the energy transiently stored in these reduced coenzymes is converted by an electron transport chain, also known as the **respiratory chain**, into the proton-motive force. We first describe the logic and components of the electron transport chain. Next we follow the path of electrons as they flow through the chain, and the mechanism of proton pumping across the mitochondrial inner membrane. We conclude this section with a discussion of the magnitude of the proton-motive force produced by electron transport and proton pumping. In Section 12.4, we will see how the proton-motive force is used to synthesize ATP.

Oxidation of NADH and $FADH_2$ Releases a Significant Amount of Energy

During electron transport, electrons are released from NADH and $FADH_2$ and eventually transferred to O_2 , forming H_2O according to the following overall reactions:

Recall that the conversion of 1 glucose molecule to CO_2 via the glycolytic pathway and citric acid cycle yields 10 NADH and 2 $FADH_2$ molecules (see Table 12-1). Oxidation of these reduced coenzymes has a total $\Delta G^{\circ'}$ of -613 kcal/mol [$10(-52.6) + 2(-43.4)$]. Thus of the potential free energy present in the chemical bonds of glucose (-686 kcal/mol), about 90 percent is conserved in the reduced coenzymes.

Why should there be two different coenzymes, NADH and FADH₂? Although many of the reactions involved in glucose and fatty acid oxidation are sufficiently energetic to reduce NAD⁺, several are not, so those reactions are coupled to reduction of FAD, which requires less energy.

The energy carried in the reduced coenzymes can be released by oxidizing them. The biochemical challenge faced by the mitochondrion is to transfer, as efficiently as possible, the energy released by this oxidation into the energy in the terminal phosphoanhydride bond in ATP.

A relatively simple one-to-one reaction involving reduction of one coenzyme molecule and synthesis of one ATP would be terribly inefficient, because the ΔG° for ATP generation from ADP and P_i is substantially less than that for the coenzyme oxidation and much energy would be lost as heat. To efficiently recover the energy, the mitochondrion converts the energy of coenzyme oxidation into a proton-motive force using a series of electron carriers, all but one of which are integral components of the inner membrane (see Figure 12-8). The proton-motive force can then be used to very efficiently generate ATP.

Electron Transport in Mitochondria Is Coupled to Proton Pumping

During electron transport from NADH and FADH₂ to O₂, protons from the mitochondrial matrix are pumped across the inner membrane. This pumping raises the pH of the mitochondrial matrix relative to the intermembrane space and cytosol and also makes the matrix more negative with respect

to the intermembrane space. In other words, the free energy released during the oxidation of NADH or FADH₂ is stored both as a proton concentration gradient and an electrical gradient across the membrane—collectively, the proton-motive force (see Figure 12-2). As we will see in Section 12.4, the movement of protons back across the inner membrane, driven by this force, is coupled to the synthesis of ATP from ADP and P_i by ATP synthase (stage IV).

The synthesis of ATP from ADP and P_i, driven by the energy released by transfer of electrons from NADH or FADH₂ to O₂, is the major source of ATP in aerobic nonphotosynthetic cells. Much evidence shows that in mitochondria and bacteria this process of *oxidative phosphorylation* depends on generation of a proton-motive force across the inner membrane (mitochondria) or bacterial plasma membrane, with electron transport, proton pumping, and ATP formation occurring simultaneously. In the laboratory, for instance, addition of O₂ and an oxidizable substrate such as pyruvate or succinate to isolated intact mitochondria results in a net synthesis of ATP if the inner mitochondrial membrane is intact. In the presence of minute amounts of detergents that make the membrane leaky, electron transport and the oxidation of these metabolites by O₂ still occurs. However, under these conditions no ATP is made, because the proton leak prevents the maintenance of the proton-motive force.

The coupling between electron transport from NADH (or FADH₂) to O₂ and proton transport across the inner mitochondrial membrane can be demonstrated experimentally with isolated, intact mitochondria (Figure 12-13). As soon as O₂ is added to a suspension of mitochondria in an otherwise O₂-free solution that contains NADH, the medium outside the mitochondria transiently becomes more acidic (increased proton concentration), because the mitochondrial outer membrane is freely permeable to protons. (Remember

EXPERIMENTAL FIGURE 12-13 Electron transfer from NADH to O₂ is coupled to proton transport across the mitochondrial membrane. If NADH is added to a suspension of mitochondria depleted of O₂, no NADH is oxidized. When a small amount of O₂ is added to the system (arrow), there is a sharp rise in the concentration of pro-

tons in the surrounding medium outside the mitochondria (decrease in pH). Thus the oxidation of NADH by O₂ is coupled to the movement of protons out of the matrix. Once the O₂ is depleted, the excess protons slowly move back into the mitochondria (powering the synthesis of ATP) and the pH of the extracellular medium returns to its initial value.

that malate-aspartate and other shuttles can convert the NADH in the solution into NADH in the matrix.) Once the O_2 is depleted by its reduction, the excess protons in the medium slowly leak back into the matrix. From analysis of the measured pH change in such experiments, one can calculate that about 10 protons are transported out of the matrix for every electron pair transferred from NADH to O_2 .

To obtain numbers for $FADH_2$, the above experiment can be repeated using succinate instead of NADH as the substrate. (Recall that oxidation of succinate to fumarate in the citric acid cycle generates $FADH_2$; see Figure 12-10). The amount of succinate added can be adjusted so that the amount of $FADH_2$ generated is equivalent to the amount of NADH in the first experiment. As in the first experiment, addition of oxygen causes the medium outside the mitochondria to become acidic, but less so than with NADH. This is not surprising because electrons in $FADH_2$ have less potential energy (43.4 kcal/mol) than electrons in NADH (52.6 kcal/mol), and thus it drives the translocation of fewer protons from the matrix and a smaller change in pH.

Electrons Flow “Downhill” Through a Series of Electron Carriers

We now examine more closely the energetically favored movement of electrons from NADH and $FADH_2$ to the final electron acceptor, O_2 . For simplicity, we will focus our discussion on NADH. In respiring mitochondria, each NADH molecule releases two electrons to the electron transport chain; these electrons ultimately reduce one oxygen atom (half of an O_2 molecule), forming one molecule of water:

As electrons move from NADH to O_2 , their electric potential declines by 1.14 V, which corresponds to 26.2 kcal/mol of electrons transferred, or ~ 53 kcal/mol for a pair of electrons. As noted earlier, much of this energy is conserved in the proton-motive force generated across the inner mitochondrial membrane.

FIGURE 12-14 Heme and iron-sulfur prosthetic groups in the electron transport chain. (a) Heme portion of cytochromes b_L and b_H , which are components of CoQH_2 -cytochrome c reductase (complex III). The same porphyrin ring (yellow) is present in all hemes. The chemical substituents attached to the porphyrin ring differ in the other cytochromes in the electron transport chain. All hemes accept and release one electron at a time. (b) Dimeric iron-sulfur cluster (Fe-S). Each Fe atom is bonded to four S atoms: two are inorganic sulfur and two are in cysteine side chains of the associated protein. All Fe-S clusters accept and release one electron at a time.

TABLE 12-2 Electron-Carrying Prosthetic Groups in the Respiratory Chain

Protein Component	Prosthetic Groups*
NADH-CoQ reductase (complex I)	FMN Fe-S
Succinate-CoQ reductase (complex II)	FAD Fe-S
CoQH_2 -cytochrome c reductase (complex III)	Heme b_L Heme b_H Fe-S Heme c_1
Cytochrome c	Heme c
Cytochrome c oxidase (complex IV)	Cu_a^{2+} Heme a Cu_b^{2+} Heme a_3

*Not included is coenzyme Q, an electron carrier that is not permanently bound to a protein complex.

SOURCE: J. W. De Pierre and L. Ernster, 1977, *Ann. Rev. Biochem.* 46:201.

Four large multiprotein complexes (complexes I–IV) compose an electron transport chain in the inner mitochondrial membrane that is responsible for the generation of the proton-motive force (see Figure 12-8, stage III). Each complex contains several *prosthetic groups* that participate in the process of moving electrons from donor molecules to acceptor molecules in coupled oxidation-reduction reactions (see Chapter 2). These small nonpeptide organic molecules or metal ions are tightly and specifically associated with the multiprotein complexes (Table 12-2).

Heme and the Cytochromes Several types of *heme*, an iron-containing prosthetic group similar to that found in hemoglobin and myoglobin (Figure 12-14a), are tightly bound

(covalently or noncovalently) to a set of mitochondrial proteins called **cytochromes**. Each cytochrome is designated by a letter, such as *a*, *b*, *c*, or *c*₁. Electron flow through the cytochromes occurs by oxidation and reduction of the Fe atom in the center of the heme molecule:

Because the heme ring in cytochromes consists of alternating double- and single-bonded atoms, a large number of resonance hybrid forms exist. These allow the extra electron delivered to the cytochrome to be delocalized throughout the heme carbon and nitrogen atoms as well as the Fe ion.

The various cytochromes have slightly different heme groups and surrounding atoms (called axial ligands), which generate different environments for the Fe ion. Therefore, each cytochrome has a different reduction potential, or tendency to accept an electron—an important property dictating the unidirectional “downhill” electron flow along the chain. Just as water spontaneously flows downhill from a higher to lower potential energy state—but not uphill—so too do electrons flow in only one direction from one heme (or other prosthetic group) to another due to their differing reduction potentials. (For more on the concept of reduction potential, *E*, see Chapter 2.) All the cytochromes, except cytochrome *c*, are components of integral membrane multiprotein complexes in the inner mitochondrial membrane.

Iron-Sulfur Clusters *Iron-sulfur clusters* are nonheme, iron-containing prosthetic groups consisting of Fe atoms bonded both to inorganic S atoms and to S atoms on cysteine residues in a protein (Figure 12-14b). Some Fe atoms in the cluster bear a +2 charge; others have a +3 charge. However, the net charge of each Fe atom is actually between +2 and +3, because electrons in their outermost orbitals together with the extra electron delivered via the transport chain are dispersed among the Fe atoms and move rapidly from one atom to another. Iron-sulfur clusters accept and release electrons one at a time.

Coenzyme Q (CoQ) *Coenzyme Q* (CoQ), also called *ubiquinone*, is the only small-molecule electron carrier in the chain that is not an essentially irreversibly protein-bound prosthetic group (Figure 12-15). It is a carrier of both protons and electrons. The oxidized quinone form of CoQ can accept a single electron to form a semiquinone, a charged free radical denoted by $\text{CoQ}^{\bullet-}$. Addition of a second electron and two protons (thus a total of two hydrogen atoms) to $\text{CoQ}^{\bullet-}$ forms dihydroubiquinone (CoQH_2), the fully reduced form. Both CoQ and CoQH_2 are soluble in phospholipids and diffuse freely in the hydrophobic center of the inner mitochondrial membrane. This is how it participates in the electron transport chain—carrying electrons and protons between the protein complexes of the chain.

We now consider in detail the multiprotein complexes which use these prosthetic groups, and the paths taken by the electrons and protons as they pass through the complexes.

FIGURE 12-15 Oxidized and reduced forms of coenzyme Q (CoQ), which can carry two protons and two electrons. Because of its long hydrocarbon “tail” of isoprene units, CoQ, also called ubiquinone, is soluble in the hydrophobic core of phospholipid bilayers and is very mobile. Reduction of CoQ to the fully reduced form, QH_2 (dihydroquinone), occurs in two steps with a half-reduced free-radical intermediate, called semiquinone.

Four Large Multiprotein Complexes Couple Electron Transport to Proton Pumping Across the Mitochondrial Inner Membrane

As electrons flow downhill from one electron carrier to the next in the electron transport chain, the energy released is used to power the pumping of protons against their electrochemical gradient across the inner mitochondrial membrane. Four large multiprotein complexes couple the movement of electrons to proton pumping: *NADH-CoQ reductase* (complex I, >40 subunits), *succinate-CoQ reductase* (complex II, 4 subunits), *CoQH₂-cytochrome c reductase* (complex III, 11 subunits), and *cytochrome c oxidase* (complex IV, 13 subunits) (Figure 12-16). Electrons from NADH flow from complex I via CoQ/CoQH_2 to complex III and then via the soluble protein cytochrome *c* (cyt *c*) to complex IV to reduce molecular oxygen (complex II is bypassed) (see Figure 12-16a); alternatively, electrons from FADH_2 flow from complex II via CoQ/CoQH_2 to complex III and then via cytochrome *c* to complex IV to reduce molecular oxygen (complex I is bypassed) (see Figure 12-16b).

As shown in Figure 12-16, CoQ accepts electrons released from *NADH-CoQ reductase* (complex I) or *succinate-CoQ reductase* (complex II) and donates them to *CoQH₂-cytochrome c reductase* (complex III). Protons are simultaneously transported from the matrix (also called the cytosolic) side of the membrane to the intermembrane space (also called the exoplasmic side). Whenever CoQ accepts electrons, it does so at a

(a) From NADH

(b) From succinate

FIGURE 12-16 The electron transport chain. Electrons (blue arrows) flow through four major multiprotein complexes (I–IV). Electron movement between complexes is mediated either by the lipid-soluble molecule coenzyme Q (CoQ, oxidized form; CoQH₂, reduced form) or the water-soluble protein cytochrome c (Cyt c). The multiple multiprotein complexes use the energy released from passing electrons to pump protons from the matrix to the intermembrane space (red arrows). **(a)** Pathway from NADH. Electrons from NADH flow through complex I, initially via a flavin mononucleotide (FMN) and then via seven iron-sulfur clusters (Fe-S), to CoQ, to which two protons bind, forming CoQH₂. Conformational changes in complex I that accompany the electron flow drive proton pumping from the matrix to the intermembrane space (red arrows). Electrons then flow via the released (and recycled) CoQH₂ to complex III, and then via Cyt c to complex IV.

A total of 10 protons are translocated per pair of electrons that flow from NADH to O₂. The protons released into the matrix space during oxidation of NADH by complex I are consumed in the formation of water from O₂ by complex IV, resulting in no net proton translocation from these reactions. **(b)** Pathway from succinate. Electrons flow from succinate to complex II via FAD/FADH₂ and iron-sulfur clusters (Fe-S), from complex II to complex III via CoQ/CoQH₂, and then to complex IV via Cyt c. Electrons released during oxidation of succinate to fumarate in complex II are used to reduce CoQ to CoQH₂ without translocating additional protons. The remainder of electron transport from CoQH₂ proceeds by the same pathway as for the NADH pathway in (a). Thus for every pair of electrons transported from succinate to O₂, six protons are translocated by complexes III and IV.

binding site on the matrix side of a protein complex, always picking up protons from the medium there. Whenever CoQH₂ releases its electrons, it does so at a site on the intermembrane space side of a protein complex, releasing protons into the fluid of the intermembrane space. Thus transport of each pair of electrons by CoQ is obligatorily coupled to movement of two protons from the matrix to the intermembrane space.

NADH-CoQ Reductase (Complex I) Electrons are transferred from NADH to CoQ by NADH-CoQ reductase (see Figure 12-16a). Electron microscopy and x-ray crystallography of complex I from both bacteria (mass ~500 kDa, with 14 subunits) and eukaryotes (~1 MDa, with 14 highly conserved core subunits shared with bacteria plus about 26–32 accessory subunits) established that it is L-shaped (Figure 12-17a). The membrane-embedded arm of the L is slightly curved, ~180 Å long, and comprises proteins with more than 60 transmembrane alpha helices. This arm has four subdomains, three of which have proteins that are members of a family of cation antiporters. The hydrophilic peripheral arm extends over 130 Å away from the membrane into the cytosolic space.

NAD⁺ is exclusively a two-electron carrier: it accepts or releases a pair of electrons simultaneously. In NADH-CoQ reductase (complex I), the NADH-binding site is at the tip of the peripheral arm (see Figure 12-17a); electrons released from NADH first flow to FMN (flavin mononucleotide), a cofactor related to FAD, then are shuttled ~95 Å down that arm through seven iron-sulfur clusters and finally to CoQ, which is bound at a site at least partially in the plane of the membrane. FMN, like FAD, can accept two electrons but does so one electron at a time.

Each transported electron undergoes a drop in potential of ~360 mV, equivalent to a ΔG° of -16.6 kcal/mol for the two electrons transported. Much of this released energy is used to transport four protons across the inner membrane per molecule of NADH oxidized by complex I. Those four protons are distinct from the two protons that are transferred to the CoQ as illustrated in Figures 12-15, 12-16a, and 12-17a. The structure of complex I suggests that the energy released by the electron transport in the peripheral arm is used to change the conformation of subunits in the membrane arm and thus mediate movement of four protons across the membrane. Three protons are likely to pass through the three cation antiporter

FIGURE 12-17 Electron and proton transport through complexes I and II. (a) Model of complex I based on its three-dimensional structure. The outline of the shape of complex I, as determined by x-ray crystallography, is shown in light blue, and distinct structural subunits are indicated by thin dashed black lines. From NADH electrons flow first to a flavin mononucleotide (FMN) and then, via seven of the nine iron-sulfur clusters (Fe-S, blue diamonds), to CoQ, to which two protons from the matrix bind (red arrow) to form CoQH₂. Conformational changes due to the electron flow, which probably include a pistonlike horizontal movement of the t-helix, drive proton

pumping through the transmembrane subunits from the matrix to the intramembrane space (red arrows). (b) Model of complex II based on its three-dimensional structure. Electrons flow from succinate to complex II via FAD/FADH₂ and iron-sulfur clusters (Fe-S, blue diamonds), and from complex II to complex III via CoQ/CoQH₂. Electrons released during oxidation of succinate to fumarate in complex II are used to reduce CoQ to CoQH₂ without translocating additional protons. [Structure of complex I adapted from C. Hunte, V. Zickermann, and U. Brandt, 2010, *Science* 329:448–451 and R. G. Efremov, R. Baradaran, and L. A. Sazanov, 2010, *Nature* 465:441–445.]

domains while the route of the forth is through a different type of domain. An ~110 Å long, kinked, transverse alpha helix (t-helix) in the membrane arm runs parallel to the plane of the membrane, potentially mechanically linking the antiporter domains to the peripheral arm (Figure 12-17a) and thereby transmitting electron-transport-induced conformational changes in the peripheral arm to the distant antiporter domains to drive proton transport.

The overall reaction catalyzed by this complex is

Succinate-CoQ Reductase (Complex II) Succinate dehydrogenase, the enzyme that oxidizes a molecule of succinate to fumarate in the citric acid cycle (and in the process generates the reduced coenzyme FADH₂), is one of the four subunits of complex II. Thus the citric acid cycle is physically as well as functionally linked to the electron transport chain. The two electrons released in conversion of succinate to fumarate are transferred first to FAD in succinate dehydrogenase, then to iron-sulfur clusters—regenerating FAD—and finally to CoQ, which binds to a cleft on the matrix side of the transmembrane portions of complex II (Figures 12-16b and 12-17b).

The pathway is somewhat reminiscent of that in complex I (Figure 12-17a).

The overall reaction catalyzed by this complex is

Although the ΔG° for this reaction is negative, the released energy is insufficient for proton pumping in addition to reduction of CoQ to form CoQH₂. Thus no protons are translocated directly across the membrane by the succinate-CoQ reductase complex, and no proton-motive force is generated in this part of the respiratory chain. Shortly we will see how the protons and electrons in the CoQH₂ molecules generated by complexes I and II contribute to the generation of the proton-motive force.

Complex II generates CoQH₂ from succinate via FAD/FADH₂-mediated redox reactions. Another set of proteins in the matrix and inner mitochondrial membrane performs a comparable set of FAD/FADH₂-mediated redox reactions to generate CoQH₂ from fatty acyl CoA. *Fatty acyl-CoA dehydrogenase*, which is a water-soluble enzyme, catalyzes the first step of the oxidation of fatty acyl CoA in the mitochondrial matrix (see Figure 12-12). There are several fatty acyl-CoA dehydrogenase enzymes with specificities for fatty acyl chains of different lengths. These enzymes mediate the initial

step in a four-step process that removes two carbons from the fatty acyl group by oxidizing the carbon in the β position of the fatty acyl chain (thus the entire process is often referred to as β -oxidation). These reactions generate acetyl CoA, which in turn enters the citric acid cycle. They also generate an FADH_2 intermediate and NADH. The FADH_2 generated remains bound to the enzyme during the redox reaction, as is the case for complex II. A water-soluble protein called *electron transfer flavoprotein (ETF)* transfers the high-energy electrons from the FADH_2 in the acyl-CoA dehydrogenase to *electron transfer flavoprotein:ubiquinone oxidoreductase (ETF:QO)*, a membrane protein that reduces CoQ to CoQH_2 in the inner membrane. This CoQH_2 intermixes in the membrane with the other CoQH_2 molecules generated by complexes I and II.

CoQH_2 -Cytochrome *c* Reductase (Complex III) A CoQH_2 generated either by complex I, complex II, or ETF:QO donates two electrons to CoQH_2 -cytochrome *c* reductase (complex III), regenerating oxidized CoQ. Concomitantly it releases into the intermembrane space two protons previously picked up by CoQ on the matrix face, generating part of the proton-motive force (see Figure 12-16). Within complex III, the released electrons first are transferred to an iron-sulfur cluster within the complex and then to cytochrome c_1 or to two *b*-type cytochromes (b_L and b_H , see Q cycle below). Finally, the two electrons are transferred sequentially to two molecules of the oxidized form of cytochrome *c*, a water-soluble peripheral protein that diffuses in the intermembrane space. For each pair of electrons transferred, the overall reaction catalyzed by the CoQH_2 -cytochrome *c* reductase complex is

The ΔG° for this reaction is sufficiently negative that two protons in addition to those from CoQH_2 are translocated from the mitochondrial matrix across the inner membrane for each pair of electrons transferred; this involves the proton-motive Q cycle, discussed below. The heme protein cytochrome *c* and the small lipid-soluble molecule CoQ play similar roles in the electron transport chain in that they both serve as mobile electron shuttles, transferring electrons (and thus energy) between the complexes of the electron transport chain.

The Q Cycle Experiments have shown that four protons are translocated across the membrane per electron pair transported from CoQH_2 through CoQH_2 -cytochrome *c* reductase (complex III). These four protons are those carried on two CoQH_2 molecules, which are converted to two CoQ molecules during the cycle. However, another CoQ molecule receives two other protons from the matrix space and is converted to one CoQH_2 molecule. Thus the net overall reaction involves the conversion of only one CoQH_2 molecule to CoQ as two electrons are transferred one at a time to two molecules of the acceptor cytochrome *c*. An evolutionarily conserved mechanism, called the *Q cycle*, is responsible for

the two-for-one transport of protons and electrons by complex III (Figure 12-18).

The substrate for complex III, CoQH_2 , is generated by several enzymes, including NADH-CoQ reductase (complex I), succinate-CoQ reductase (complex II), *electron transfer*

Net Q cycle (sum of reactions at Q_o and Q_i):

Per 2 e^- transferred through complex III to cytochrome *c*, 4 H^+ released to the intermembrane space

FIGURE 12-18 The Q cycle. The Q cycle of complex III uses the net oxidation of one CoQH_2 molecule to transfer four protons into the intermembrane space and two electrons to two cytochrome *c* molecules. The cycle begins when a molecule from the combined pool of reduced CoQH_2 in the membrane binds to the Q_o site on the *intermembrane space (outer) side* of the transmembrane portion of complex III (step 1). There, CoQH_2 releases two protons into the intermembrane space (step 2a), and two electrons and the resulting CoQ dissociate (step 5). One of the electrons is transported, via an iron-sulfur protein and cytochrome c_1 , directly to cytochrome *c* (step 2b). (Recall that each cytochrome *c* shuttles one electron from complex III to complex IV.) The other electron moves through cytochromes b_L and b_H and partially reduces an oxidized CoQ molecule bound to the second, Q_i , site on the *matrix (inner) side* of the complex, forming a CoQ semiquinone anion, $Q^{\cdot-}$ (step 4). The process is repeated with the binding of a second CoQH_2 at the Q_o site (step 5), proton release (step 6a), reduction of another cytochrome *c* (step 6b), and addition of the other electron to the $Q^{\cdot-}$ bound at the Q_i site (step 7). There, the addition of two protons from the matrix yields a fully reduced CoQH_2 molecule at the Q_i site, which then dissociates (steps 8 and 9), freeing the Q_i to bind a new molecule of CoQ (step 10) and begin the Q cycle over again. [Adapted from B. Trumpower, 1990, *J. Biol. Chem.* **265**:11409, and E. Darrouzet et al., 2001, *Trends Biochem. Sci.* **26**:445.]

flavoprotein:ubiquinone oxidoreductase (ETF:QO, during β -oxidation), and, as we shall see, by complex III itself.

As shown in Figure 12-18, in one turn of the Q cycle, two molecules of CoQH_2 are oxidized to CoQ at the Q_o site and release a total of four protons into the intermembrane space, but at the Q_i site one molecule of CoQH_2 is regenerated from CoQ and two additional protons from the matrix space. The translocated protons are all derived from CoQH_2 which obtained its protons from the matrix as described above. Although seemingly cumbersome, the Q cycle optimizes the number of protons pumped per pair of electrons moving through complex III. The Q cycle is found in all plants and animals, as well as in bacteria. Its formation at a very early stage of cellular evolution was likely essential for the success of all life-forms, as a way of converting the potential energy in reduced coenzyme Q into the maximum proton-motive force across a membrane. In turn this maximizes the number of ATP molecules synthesized from each electron that moves down the electron transport chain from NADH or FADH_2 to oxygen.

How are the two electrons released from CoQH_2 at the Q_0 site directed to different acceptors, either to Fe-S, cytochrome c_1 , and then cytochrome c (upward pathway in Figure 12-18), or alternatively to cytochrome b_L , cytochrome b_H , and then CoQ at the Q_I site (downward pathway in Figure 12-18)? The mechanism involves a flexible hinge in the Fe-S-containing protein subunit of complex III. Initially the Fe-S cluster is close enough to the Q_0 site to pick up an electron from CoQH_2 bound there. Once this happens, a segment of the protein containing this Fe-S cluster swings the cluster away from the Q_0 site to a position near enough to the heme on cytochrome c_1 for electron transfer to occur. With the Fe-S subunit in this alternate conformation, the second electron released from CoQH_2 bound to the Q_0 site cannot move to the Fe-S cluster—it is too far away, so it takes an alternative path open to it via a somewhat less thermodynamically favored route to cytochrome b_L and through cytochrome b_H to the CoQ at the Q_I site.

Cytochrome *c* Oxidase (Complex IV) Cytochrome *c*, after being reduced by one electron from CoQH₂-cytochrome *c* reductase (complex III), is reoxidized as it transports its electron to cytochrome *c* oxidase (complex IV) (see Figure 12-16). Mitochondrial cytochrome *c* oxidases contain 13 different subunits, but the catalytic core of the enzyme consists of only three subunits. The functions of the remaining subunits are not well understood. Bacterial cytochrome *c* oxidases contain only the three catalytic subunits. In both mitochondria and bacteria, four molecules of reduced cytochrome *c* bind, one at a time, to the oxidase. An electron is transferred from the heme of each cytochrome *c*, first to the pair of copper ions called Cu_a²⁺, then to the heme in cytochrome *a*, and next to the Cu_b²⁺ and the heme in cytochrome *a*₃ that together make up the oxygen reduction center. The four electrons are finally passed to O₂, the ultimate electron acceptor, yielding four H₂O, which together with CO₂ is one of the end products of the overall oxidation pathway. (Note that, for

simplicity, Figure 12-16 shows only two electrons moving and $\frac{1}{2}$ O₂ being reduced.) Proposed intermediates in oxygen reduction include the peroxide anion (O₂²⁻) and probably the hydroxyl radical (OH·), as well as unusual complexes of iron and oxygen atoms. These intermediates would be harmful to the cell if they escaped from complex IV, but they do so only rarely (see the discussion of reactive oxygen species below). During transport of four electrons through the cytochrome *c* oxidase complex, four protons from the matrix space are translocated across the membrane. Thus, complex IV transports only one proton per electron transferred, whereas complex II, using the Q cycle, transports two protons per electron transferred. However, the mechanism by which complex IV translocates these protons is not known.

For each four electrons transferred, the overall reaction catalyzed by cytochrome *c* oxidase is

FIGURE 12-19 Changes in redox potential and free energy during stepwise flow of electrons through the respiratory chain. Blue arrows indicate electron flow; red arrows, translocation of protons across the inner mitochondrial membrane. Electrons pass through the multiprotein complexes from those at a lower reduction potential to those with a higher (more positive) reduction potential (left scale), with a corresponding reduction in free energy (right scale). The energy released as electrons flow through three of the complexes is sufficient to power the pumping of H^+ ions across the membrane, establishing a proton-motive force.

is +220 mV ($\Delta G'^{\circ} = -5.1$ kcal/mol) for transfer of one electron. Thus this partial reaction tends to proceed toward the right, that is, toward the reduction of cytochrome *c* (Fe^{3+}) to cytochrome *c* (Fe^{2+}).

The final reaction in the respiratory chain, the reduction of O_2 to H_2O

has a standard reduction potential of +816 mV ($\Delta G'^{\circ} = -37.8$ kcal/mol for transfer of two electrons), the most positive in the whole series; thus this reaction also tends to proceed toward the right.

As illustrated in Figure 12-19, the steady increase in E'° values, and the corresponding decrease in $\Delta G'^{\circ}$ values, of the carriers in the electron transport chain favors the flow of electrons from NADH and FADH₂ (generated from succinate) to oxygen. The energy released as electrons flow “downhill” energetically through the electron transport chain complexes drives the pumping of protons against their concentration gradient across the mitochondrial inner membrane.

The Multiprotein Complexes of the Electron Transport Chain Assemble into Supercomplexes

Over 50 years ago Britton Chance proposed that electron transport complexes might assemble into large supercomplexes. Doing so would bring the complexes into close and highly organized proximity, which might improve the speed and efficiency of the overall process. Indeed, genetic, biochemical, and biophysical studies have provided very strong evidence for the existence of electron transport chain supercomplexes. These studies involved gel electrophoretic methods called blue native (BN)-PAGE and colorless native (CN)-PAGE, which permit separation of very large macromolecular protein complexes, and electron microscopic analysis of their three-dimensional structures. One such supercomplex contains one copy of complex I, a dimer of complex III (III_2), and one or more copies of complex IV (Figure 12-20). One supercomplex that contains all of the components thought to play a role in respiration—complexes I–IV, ubiquinone (CoQ), and cytochrome *c*—was isolated from BN-PAGE gels and shown to transfer electrons from NADH

EXPERIMENTAL FIGURE 12-20 Electrophoresis and electron microscopic imaging identifies an electron transport chain supercomplex containing complexes I, III, and IV. (a) Membrane proteins in isolated bovine heart mitochondria were solubilized with a detergent, and the complexes and supercomplexes were separated by gel electrophoresis using the blue native (BN)-PAGE method. Each blue-stained band within the gel represents the indicated protein complex or supercomplex, with III₂ representing a dimer of complex III. Intensity of the blue stain is approximately proportional to the amount

of complex or supercomplex present. (b) Supercomplex I/III₂/IV was extracted from the gel, and the particles were negatively stained with 1% uranyl acetate and visualized by transmission electron microscopy. Images of 228 particles were combined at a resolution of ~3.4 nm to generate an averaged image of the complex viewed from the side in the plane of the membrane. Approximate locations of the complex III dimer and complex IV are indicated by dashed ovals; the outline of complex I is also indicated by a dashed line (white). Scale bar is 10 nm. [Adapted from E. Schafer et al., 2006, *J. Biol. Chem.* **281**(22):15370–15375.]

to O₂; in other words, this supercomplex can respire—it is a respirasome.

The unique phospholipid *cardiolipin* (diphosphatidyl glycerol) appears to play an important role in the assembly and function of these supercomplexes. Generally not observed

in other membranes of eukaryotic cells, cardiolipin has been observed to bind to integral membrane proteins of the inner membrane (e.g., complex II). Genetic and biochemical studies in yeast mutants in which cardiolipin synthesis is blocked have established that cardiolipin contributes to the formation and activity of mitochondrial supercomplexes, and thus it has been called the glue that holds together the electron transport chain, though the precise mechanism remains to be defined. In addition, there is evidence that cardiolipin may influence the inner membrane's binding and permeability to protons and consequently the proton-motive force.

Reactive Oxygen Species (ROS) Are Toxic By-products of Electron Transport That Can Damage Cells

About 1–2 percent of the oxygen metabolized by aerobic organisms, rather than being converted to water, is partially reduced to the superoxide anion radical (O₂^{•−}, where the “dot” represents an unpaired electron). Radicals are atoms that have one or more unpaired electrons in an outer (valence) shell, or molecules that contain such an atom. Many, though not all, radicals are generally highly chemically reactive, altering the structures and properties of those molecules with which they react. The products of such reactions often are themselves radicals and thus can propagate a chain reaction that alters many additional molecules. Superoxide and other highly reactive oxygen-containing molecules, both radicals (e.g., O₂^{•−}) and non-radicals (hydrogen peroxide, H₂O₂) are called *reactive oxygen species* (ROS). ROS are of great interest because they can react with and thus damage many key biological molecules, including lipids (particularly unsaturated fatty acids and their derivatives), proteins, and DNA, and thus severely interfere with their normal functions. At moderate to high levels, ROS contribute to what is often called *cellular oxidative stress* and can be highly toxic. Indeed, ROS are purposefully generated by body defense cells (e.g., macrophages, neutrophils) to kill pathogens. In humans, excessive or inappropriate generation of ROS has been implicated in many diverse diseases, including heart failure, neurodegenerative diseases, alcohol-induced liver disease, diabetes, and aging.

Although there are several mechanisms for generating ROS in cells, the major source in eukaryotic cells is electron

transport in the mitochondria (or in chloroplasts as described below). Electrons passing through the mitochondrial electron transport chain can have sufficient energy to reduce molecular oxygen (O_2) to form superoxide anions (Figure 12-21, *top*). This can only occur, however, when molecular oxygen comes in close contact with the reduced electron carriers (iron, FMN, $CoQH_2$) in the chain. Usually such contact is prevented by sequestration of the carriers within the proteins involved. However, there are some sites (particularly in complex I and CoQ^+ , see Figure 12-15) and some conditions (e.g., high $NADH/NAD^+$ ratio in the matrix, high proton-motive force when ATP is not generated) when electrons can more readily “leak” out of the chain and reduce O_2 to $O_2^{\cdot -}$.

Superoxide anion is an especially unstable and reactive ROS. Mitochondria have evolved several defense mechanisms that help protect against $O_2^{\cdot -}$ toxicity, including the use of enzymes that inactivate superoxide, first by converting it to H_2O_2 (Mn-containing superoxide dismutase, SOD) and then to H_2O (catalase) (Figure 12-21). Because $O_2^{\cdot -}$ is so highly reactive and toxic, SOD and catalase are some of the fastest enzymes known. SOD is found within mitochondria and other cellular compartments. Hydrogen peroxide itself is a ROS that can diffuse readily across membranes and react with molecules throughout the cell. It can also be converted by certain metals such as Fe^{2+} into the even more dangerous

hydroxyl radical ($OH^{\cdot}$). Thus cells depend on the inactivation of H_2O_2 by catalase and other enzymes, such as peroxiredoxin and glutathione peroxidase, which also detoxify the lipid hydroperoxide products formed when ROS react with unsaturated fatty acyl groups. Small molecule antioxidant radical scavengers such as vitamin E and α -lipoic acid also protect against oxidative stress. Although in many cells catalase is located only in peroxisomes, in heart muscle cells it is found in mitochondria. This is not surprising, because the heart is the most oxygen-consuming organ per gram weight in mammals.

As the rate of ROS production by mitochondria and chloroplasts reflects the metabolic state of these organelles (e.g., size of proton-motive force, $NADH/NAD^+$ ratio), cells have developed ROS-sensing systems, such as ROS/redox-sensitive transcription factors, to monitor the metabolic state of these organelles and respond accordingly, for example by changing the rate of transcription of nuclear genes that encode organelle-specific proteins. ■

Experiments Using Purified Electron Transport Chain Complexes Established the Stoichiometry of Proton Pumping

The multiprotein complexes of the electron transport chain that are responsible for proton pumping have been identified by selectively extracting mitochondrial membranes with detergents, isolating each of the complexes in nearly pure form, and then preparing artificial phospholipid vesicles (liposomes) containing each complex. When an appropriate electron donor and electron acceptor are added to such liposomes, a change in pH of the medium will occur if the embedded complex transports protons (Figure 12-22). Studies of this type indicate that NADH-CoQ reductase (complex I) translocates four protons per pair of electrons transported, whereas cytochrome *c* oxidase (complex IV) translocates two protons per electron pair transported.

Current evidence suggests that a total of 10 protons are transported from the matrix space across the inner mitochondrial membrane for every electron pair that is transferred from NADH to O_2 (see Figure 12-16). Because succinate-CoQ reductase (complex II) does not transport protons and complex I is bypassed when the electrons come from succinate-derived $FADH_2$, only six protons are transported across the membrane for every electron pair that is transferred from this $FADH_2$ to O_2 .

The Proton-Motive Force in Mitochondria Is Due Largely to a Voltage Gradient Across the Inner Membrane

The main result of the electron transport chain is the generation of the proton-motive force (pmf), which is the sum of a transmembrane proton concentration (pH) gradient and electric potential, or voltage gradient, across the mitochondrial inner membrane. The relative contribution of the two

FIGURE 12-21 Generation and inactivation of toxic reactive oxygen species. Electrons from the electron transport chains of mitochondria and chloroplasts as well as some generated through other enzymatic reactions reduce molecular oxygen (O_2), forming the highly reactive radical anion superoxide ($O_2^{\cdot -}$). Superoxide is rapidly converted by superoxide dismutase (SOD) to hydrogen peroxide (H_2O_2), which in turn can be converted by metal ions such as Fe^{2+} to hydroxyl radicals ($OH^{\cdot}$) or inactivated to water by enzymes such as catalase. Because of their high chemical reactivity $O_2^{\cdot -}$, H_2O_2 , $OH^{\cdot}$, and similar molecules are called reactive oxygen species (ROS). They cause oxidative and free radical damage to many biomolecules, including lipids, proteins, and DNA. This damage leads to cellular oxidative stress that can cause disease and, if sufficiently severe, can kill cells.

EXPERIMENTAL FIGURE 12-22 Electron transfer from reduced cytochrome *c* to O_2 via cytochrome *c* oxidase (complex IV) is coupled to proton transport. The oxidase complex is incorporated into liposomes with the binding site for cytochrome *c* positioned on the outer surface. (a) When O_2 and reduced cytochrome *c* are added, electrons are transferred to O_2 to form H_2O and protons are transported from the inside to the medium outside of the vesicles. A drug called valinomycin was added to the medium to dissipate the voltage gradient generated by the translocation of H^+ , which would otherwise reduce the number of protons moved across the membrane. (b) Monitoring of the medium's pH reveals a sharp drop in pH following addition of O_2 . As the reduced cytochrome *c* becomes fully oxidized, protons leak back into the vesicles, and the pH of the medium returns to its initial value. Measurements show that two protons are transported per O atom reduced. Two electrons are needed to reduce one O atom, but cytochrome *c* transfers only one electron; thus two molecules of Cyt *c*²⁺ are oxidized for each O reduced. [Adapted from B. Reynafarje et al., 1986, *J. Biol. Chem.* **261**:8254.]

components to the total pmf has been determined experimentally, and depends on the permeability of the membrane to ions other than H^+ . A significant voltage gradient can develop only if the membrane is poorly permeable to other cations and to anions. Otherwise, anions would leak across from the matrix to the intermembrane space along with the protons and prevent a voltage gradient from forming. Similarly, cations leaking across from the intermembrane space

to the matrix (exchange of like charge) would also short-circuit voltage gradient formation. Indeed, the inner mitochondrial membrane is poorly permeable to other ions. Thus proton pumping generates a voltage gradient that makes it energetically difficult for additional protons to move across because of charge repulsion. As a consequence, proton pumping by the electron transport chain establishes a robust voltage gradient in the context of a rather small pH gradient.

Because mitochondria are much too small to be impaled with electrodes, the electric potential and pH gradient across the inner mitochondrial membrane cannot be directly measured. However, the electric potential can be measured indirectly by adding radioactive $^{42}\text{K}^+$ ions and a trace amount of valinomycin to a suspension of respiring mitochondria and measuring the amount of radioactivity that accumulates in the matrix. Although the inner membrane is normally impermeable to K^+ , valinomycin is an *ionophore*, a small lipid-soluble molecule that selectively binds a specific ion (in this case, K^+) and carries it across otherwise impermeable membranes. In the presence of valinomycin, $^{42}\text{K}^+$ equilibrates across the inner membrane of isolated mitochondria in accordance with the electric potential: the more negative the matrix side of the membrane, the more $^{42}\text{K}^+$ will be attracted to and accumulate in the matrix.

At equilibrium, the measured concentration of radioactive K^+ ions in the matrix, $[\text{K}_{\text{in}}]$, is about 500 times greater than that in the surrounding medium, $[\text{K}_{\text{out}}]$. Substitution of this value into the Nernst equation (Chapter 11) shows that the electric potential E (in mV) across the inner membrane in respiring mitochondria is -160 mV, with the matrix (inside) negative:

$$E = -59 \log \frac{[\text{K}_{\text{in}}]}{[\text{K}_{\text{out}}]} = -59 \log 500 = -160 \text{ mV}$$

Researchers can measure the matrix (inside) pH by trapping pH-sensitive fluorescent dyes inside vesicles formed from the inner mitochondrial membrane, with the matrix side of the membrane facing inward. They also can measure the pH outside of the vesicles (equivalent to the intermembrane space) and thus determine the pH gradient (ΔpH), which turns out to be ~ 1 pH unit. Because a difference of one pH unit represents a tenfold difference in H^+ concentration, according to the Nernst equation a pH gradient of one unit across a membrane is equivalent to an electric potential of 59 mV at 20 °C. Thus, knowing the voltage and pH gradients, we can calculate the proton-motive force, pmf, as

$$\text{pmf} = \Psi - \left(\frac{RT}{F} \times \Delta\text{pH} \right) = \Psi - 59 \Delta\text{pH}$$

where R is the gas constant of 1.987 cal/(degree $\cdot$ mol), T is the temperature (in degrees Kelvin), F is the Faraday constant [23,062 cal/(V $\cdot$ mol)], and Ψ is the transmembrane electric potential; Ψ and pmf are measured in millivolts. The electric potential Ψ across the inner membrane is -160 mV (negative inside matrix) and ΔpH is equivalent to ~ 60 mV. Thus the total pmf is -220 mV, with the transmembrane electric potential responsible for about 73 percent of the total.

KEY CONCEPTS of Section 12.3

The Electron Transport Chain and Generation of the Proton-Motive Force

- By the end of the citric acid cycle (stage II), much of the energy originally present in the covalent bonds of glucose and fatty acids is converted into high-energy electrons in the reduced coenzymes NADH and FADH₂. The energy from these electrons is used to generate the proton-motive force.
- In the mitochondrion, the proton-motive force is generated by coupling electron flow (from NADH and FADH₂ to O₂) to the uphill transport of protons from the matrix across the inner membrane to the intermembrane space. This process together with the synthesis of ATP from ADP and P_i driven by the proton-motive force is called oxidative phosphorylation.
- As electrons flow from FADH₂ and NADH to O₂ they pass through multiprotein complexes. The four major complexes are NADH-CoQ reductase (complex I), succinate-CoQ reductase (complex II), CoQH₂-cytochrome *c* reductase (complex III), and cytochrome *c* oxidase (complex IV) (see Figure 12-16).
- Each complex contains one or more electron-carrying prosthetic groups: iron-sulfur clusters, flavins, heme groups, and copper ions (see Table 12-2). Cytochrome *c*, which contains heme, and coenzyme Q (CoQ), a lipid-soluble small molecule, are mobile carriers that shuttle electrons between the complexes.
- Complexes I, III, and IV pump protons from the matrix into the intermembrane space. Complexes I and II reduce CoQ to CoQH₂, which carries protons and high-energy electrons to complex III. The heme protein cytochrome *c* carries electrons from complex III to complex IV, which uses them to pump protons and reduce molecular oxygen to water.
- The high-energy electrons from NADH enter the electron transport chain through complex I, whereas the high-energy electrons from FADH₂ (derived from succinate in the citric acid cycle) enter the electron transport chain through complex II. Additional electrons derived from FADH₂ by the initial step of fatty acyl-CoA β -oxidation increase the supply of CoQH₂ available for electron transport.
- The Q cycle allows four protons to be translocated per pair of electrons moving through complex III (see Figure 12-18).
- Each electron carrier in the chain accepts an electron or electron pair from a carrier with a less positive reduction potential and transfers the electron to a carrier with a more positive reduction potential. Thus the reduction potentials of electron carriers favor unidirectional, “downhill,” electron flow from NADH and FADH₂ to O₂ (see Figure 12-19).
- Within the inner membrane, electron transport complexes assemble into supercomplexes held together by cardiolipin, a specialized phospholipid. Supercomplex formation may enhance the speed and efficiency of generation of the proton-motive force.

- Reactive oxygen species (ROS) are toxic by-products of the electron transport chain that can modify and damage proteins, DNA, and lipids. Specific enzymes (e.g., glutathione peroxidase, catalase) and small molecule antioxidants (e.g., vitamin E) help protect against ROS-induced damage (see Figure 12-21). ROS can also be used as intracellular signaling molecules.
- A total of 10 H⁺ ions are translocated from the matrix across the inner membrane per electron pair flowing from NADH to O₂ (see Figure 12-16), whereas 6 H⁺ ions are translocated per electron pair flowing from FADH₂ to O₂.
- The proton-motive force is due largely to a voltage gradient across the inner membrane produced by proton pumping; the pH gradient plays a quantitatively less important role.

12.4 Harnessing the Proton-Motive Force to Synthesize ATP

The hypothesis that a proton-motive force across the inner mitochondrial membrane is the immediate source of energy for ATP synthesis was proposed in 1961 by Peter Mitchell. Virtually all researchers studying oxidative phosphorylation and photosynthesis initially rejected his *chemiosmotic hypothesis*. They favored a mechanism similar to the then well-elucidated substrate-level phosphorylation in glycolysis, in which chemical transformation of a substrate molecule (in the case of glycolysis, phosphoenolpyruvate) is directly coupled to ATP synthesis. Despite intense efforts by a large number of investigators, however, compelling evidence for such a substrate-level phosphorylation-mediated mechanism was never observed.

Definitive evidence supporting Mitchell's hypothesis depended on developing techniques to purify and reconstitute organelle membranes and membrane proteins. The experiment with vesicles made from chloroplast thylakoid membranes (equivalent to the inner membrane of mitochondria) containing **ATP synthase**, outlined in Figure 12-23, was one of several demonstrating that this protein is an ATP-generating enzyme and that ATP generation is dependent on proton movement down an electrochemical gradient. It turns out that the protons actually move *through* the ATP synthase as they traverse the membrane.

As we shall see, the ATP synthase is a multiprotein complex that can be subdivided into two subcomplexes called F₀ (containing the transmembrane portions of the complex) and F₁ (containing the globular portions of the complex that sit above the membrane and point toward the matrix space in mitochondria). Thus the ATP synthase is often also called the **F₀F₁ complex**; we will use the terms interchangeably.

The Mechanism of ATP Synthesis Is Shared Among Bacteria, Mitochondria, and Chloroplasts

Although bacteria lack internal membranes, aerobic bacteria nonetheless carry out oxidative phosphorylation by the same processes that occur in eukaryotic mitochondria and

EXPERIMENTAL FIGURE 12-23 Synthesis of ATP by ATP synthase depends on a pH gradient across the membrane. Isolated chloroplast thylakoid vesicles containing ATP synthase (F_0F_1 particles) were equilibrated in the dark with a buffered solution at pH 4.0. When the pH in the thylakoid lumen became 4.0, the vesicles were rapidly mixed with a solution at pH 8.0 containing ADP and P_i . A burst of ATP synthesis accompanied the transmembrane movement of protons driven by the 10,000-fold H^+ concentration gradient (10^{-4} M versus 10^{-8} M). In similar experiments using “inside-out” preparations of mitochondrial membrane vesicles, an artificially generated membrane electric potential also resulted in ATP synthesis.

chloroplasts (Figure 12-24). Enzymes that catalyze the reactions of both the glycolytic pathway and the citric acid cycle are present in the cytosol of bacteria; enzymes that oxidize NADH to NAD^+ and transfer the electrons to the ultimate acceptor O_2 reside in the bacterial plasma membrane. The movement of electrons through these membrane carriers is coupled to the pumping of protons out of the cell. The movement of protons back into the cell, down their concentration gradient through ATP synthase, drives the synthesis of ATP. The bacterial ATP synthase (F_0F_1 complex) is essentially identical in structure and function to the mitochondrial and chloroplast ATP synthases but is simpler to purify and study.

Why is the mechanism of ATP synthesis shared among both prokaryotic organisms and eukaryotic organelles? Primitive aerobic bacteria were probably the progenitors of both mitochondria and chloroplasts in eukaryotic cells (Figure 12-25). According to this *endosymbiont hypothesis*, the

FIGURE 12-24 ATP synthesis by chemiosmosis is similar in bacteria, mitochondria, and chloroplasts. In chemiosmosis, a proton-motive force generated by proton pumping across a membrane is used to power ATP synthesis. The mechanism and membrane orientation of the process are similar in bacteria, mitochondria, and chloroplasts. In each illustration, the membrane surface facing a shaded area is a cytosolic face; the surface facing an unshaded, white area is an exoplasmic face. Note that the cytosolic face of the bacterial plasma membrane, the matrix face of the inner mitochondrial membrane, and the stromal face of the thylakoid membrane are all equivalent. During electron transport, protons are always pumped from the cytosolic face to the exoplasmic face, creating a proton concentration gradient (exoplasmic face $>$ cytosolic face) and an electric potential (negative cytosolic face and positive exoplasmic face) across the membrane. During the synthesis of ATP, protons flow in the reverse direction (down their electrochemical gradient) through ATP synthase (F_0F_1 complex), which protrudes in a knob at the cytosolic face in all cases.

FIGURE 12-25 Endosymbiont hypothesis for the evolutionary origin of mitochondria and chloroplasts. Endocytosis of a bacterium by an ancestral eukaryotic cell (step 1) would generate an organelle with two membranes, the outer membrane derived from the eukaryotic plasma membrane and the inner one from the bacterial membrane (step 2). The F_1 subunit of ATP synthase, localized to the cytosolic face of the bacterial membrane, would then face the matrix of the evolving

mitochondrion (left) or chloroplast (right). Budding of vesicles from the inner chloroplast membrane, such as occurs during development of chloroplasts in contemporary plants, would generate the thylakoid membranes with the F_1 subunit remaining on the cytosolic face, facing the chloroplast stroma (step 3). Membrane surfaces facing a shaded area are cytosolic faces; surfaces facing an unshaded area are exoplasmic faces.

inner mitochondrial membrane would be derived from the bacterial plasma membrane with its cytosolic face pointing toward what became the matrix space of the mitochondrion. Similarly, in plants the progenitor's plasma membrane became the chloroplast's thylakoid membrane and its cytosolic face pointed toward what became the stromal space of the chloroplast. In all cases, ATP synthase is positioned with the globular F_1 domain, which catalyzes ATP synthesis, on the cytosolic face of the membrane, so ATP is always formed on the cytosolic face of the membrane (see Figure 12-24). Protons always flow through ATP synthase from the exoplasmic to the cytosolic face of the membrane. This flow is driven by the proton motive force. Invariably, the cytosolic face has a negative electric potential relative to the exoplasmic face.

In addition to ATP synthesis, the proton-motive force across the bacterial plasma membrane is used to power other processes, including the uptake of nutrients such as sugars (using proton/sugar symporters) and the rotation of bacterial flagella. Chemiosmotic coupling thus illustrates an important principle introduced in our discussion of active transport in Chapter 11: *the membrane potential, the concentration gradients of protons (and other ions) across a membrane, and the phosphoanhydride bonds in ATP are equivalent and interconvertible forms of chemical potential energy.* Indeed, ATP synthesis through ATP synthase can be thought of as active transport in reverse.

ATP Synthase Comprises F_0 and F_1 Multiprotein Complexes

With general acceptance of Mitchell's chemiosmotic mechanism, researchers turned their attention to the structure and operation of ATP synthase. The complex has two principal components, F_0 and F_1 , both of which are multimeric proteins

(Figure 12-26a). The F_0 component contains three types of integral membrane proteins, designated a, b, and c. In bacteria and in yeast mitochondria the most common subunit stoichiometry is $a_1b_2c_{10}$, but F_0 complexes in animal mitochondria have 12 c subunits and those in chloroplasts have 14. In all cases the c subunits form a doughnut-shaped ring ("c ring") in the plane of the membrane. The a and two b subunits are rigidly linked to one another but not to the c ring, a critical feature of the protein to which we will return shortly.

The F_1 portion is a water-soluble complex of five distinct polypeptides with the composition $\alpha_3\beta_3\gamma\delta\epsilon$ that is normally firmly bound to the F_0 subcomplex at the surface of the membrane. The lower end of the rodlike γ subunit of the F_1 subcomplex is a coiled coil that fits into the center of the c-subunit ring of F_0 and appears rigidly attached to it. Thus when the c-subunit ring rotates, the rodlike γ subunit moves with it. The F_1 ϵ subunit is rigidly attached to γ and also forms tight contacts with several of the c subunits of F_0 . The α and β subunits are responsible for the overall globular shape of the F_1 subcomplex and associate in alternating order to form a hexamer, $\alpha\beta\alpha\beta\alpha\beta$, or $(\alpha\beta)_3$, which rests atop the single long γ subunit. The F_1 δ subunit is permanently linked to one of the F_1 α subunits and also binds to the b subunit of F_0 . Thus the F_0 a and b subunits and the δ subunit and $(\alpha\beta)_3$ hexamer of the F_1 complex form a rigid structure anchored in the membrane. The rodlike b subunits form a "stator" that prevents the $(\alpha\beta)_3$ hexamer from moving while it rests on the γ subunit, whose rotation together with the c subunits of F_0 plays an essential role in the ATP synthesis mechanism described below.

When ATP synthase is embedded in a membrane, the F_1 component forms a knob that protrudes from the cytosolic (in the mitochondrion this is the matrix) face. Because F_1 separated from membranes is capable of catalyzing ATP

FIGURE 12-26 Structure of ATP synthase (the F_0F_1 complex) in the bacterial plasma membrane and mechanism of proton translocation across the membrane. (a) The F_0 membrane-embedded portion of ATP synthase is built of three integral membrane proteins: one copy of **a**, two copies of **b**, and on average 10 copies of **c** arranged in a ring in the plane of the membrane. Two proton half-channels in subunit **a** mediate proton movement across the membrane (proton path indicated by red arrows). Half-channel I allows protons to move one at a time from the exoplasmic medium to the negatively charged side chain of Asp-61 in the center of a **c** subunit near the middle of the membrane. The proton-binding site in each **c** subunit is represented as a white circle with a blue “—” representing the negative charge on the side chain of Asp-61. Half-channel II permits protons to move from the Asp-61 of an adjacent **c** subunit into the cytosolic medium. The F_1 portion of ATP synthase contains three copies each of subunits α and β that form a hexamer resting atop the single rod-shaped γ subunit, which is inserted into the **c** ring of F_0 . The ϵ subunit is rigidly attached to the γ subunit and also to several of the **c** subunits. The δ subunit permanently links one of the α subunits in the F_1 complex to the **b** subunit of F_0 . Thus the F_0 **a** and **b**

subunits and the F_1 δ subunit and $(\alpha\beta)_3$ hexamer form a rigid structure anchored in the membrane (orange). During proton flow, the **c** ring and the attached F_1 ϵ and γ subunits rotate as a unit (green), causing conformation changes in the F_1 β subunits, leading to ATP synthesis. (b) Potential mechanism of proton translocation. Step **1**: A proton from the exoplasmic space enters half-channel I and moves toward the “empty” (unprotonated) Asp-61 proton-binding site. The negative charge (blue “—”) on the unprotonated side chain Asp-61 is balanced, in part, by a positive charge on the side chain of Arg-210 (red “+”). Step **2**: The proton fills the empty proton-binding site and simultaneously displaces the Arg-210 side chain, which swings over to the filled proton-binding site on the adjacent **c** subunit. As a consequence the proton bound at that adjacent site is displaced. Step **3**: The displaced adjacent proton moves through half-channel II and is released into the cytosolic space, leaving an empty proton-binding site on Asp-61. Step **4**: Counterclockwise rotation of the entire **c** ring moves the “empty” **c** subunit over half-channel I. Step **5**: the process is repeated. [Adapted from M. J. Schnitzer, 2001, *Nature* **410**:878; P. D. Boyer, 1999, *Nature* **402**:247; and C. von Ballmoos, A. Wiedenmann, and P. Dimroth, 2009, *Ann. Rev. Biochem.* **78**:649–672.]

hydrolysis (ATP conversion to ADP plus P_i) in the absence of the F_0 component, it has been called the F_1 ATPase; however, its function in cells is the reverse, to synthesize ATP. ATP hydrolysis is a spontaneous process ($\Delta G < 0$); thus energy is required to drive the ATPase “in reverse” and generate ATP.

Rotation of the F_1 γ Subunit, Driven by Proton Movement Through F_0 , Powers ATP Synthesis

Each of the three β subunits in the globular F_1 portion of the complete F_0F_1 complex can bind ADP and P_i and catalyze the endergonic synthesis of ATP when coupled to the flow of

protons from the exoplasmic medium (intermembrane space in the mitochondrion) to the cytosolic (matrix) medium. However, the coupling between proton flow and ATP synthesis must not occur in the same portions of the protein, because the nucleotide-binding sites on the β subunits of F_1 , where ATP synthesis occurs, are 9–10 nm from the surface of the mitochondrial membrane. The most widely accepted model for ATP synthesis by the F_0F_1 complex—the *binding-change mechanism*—posits just such an indirect coupling (Figure 12-27).

According to this mechanism, energy released by the “downhill” movement of protons through F_0 directly powers rotation of the **c**-subunit ring together with its attached γ and

FIGURE 12-27 The binding-change mechanism of ATP synthesis from ADP and P_i . This view is looking up at F_1 from the membrane surface (see Figure 12-26). As the γ subunit rotates by 120° in the center, each of the otherwise identical F_1 β subunits alternates between three conformational states (O, open with oval representation of the binding site; L, loose with a rectangular binding site; T, tight with a triangular site) that differ in their binding affinities for ATP, ADP, and P_i . The cycle begins (upper left) when ADP and P_i bind loosely to one of the three β subunits (here, arbitrarily designated β_1) whose nucleotide-binding site is in the O (open) conformation. Proton flux through the F_0 portion of the protein powers a 120° rotation of the γ subunit (relative to the fixed β subunits) (step **1**). This causes the rotating γ subunit, which is asymmetric, to push differentially against the β subunits, resulting in a conformational change and an increase in the binding affinity of the β_1 subunit for ADP and P_i (from O $\rightarrow$ L), an increase in the binding affinity of the β_3 subunit for ADP and P_i that were previously bound (from L $\rightarrow$ T),

and a decrease in the binding affinity of the β_2 subunit for a previously bound ATP (from T $\rightarrow$ O), causing release of the bound ATP. Step **2**: Without additional rotation the ADP and P_i in the T site (here the β_3 subunit) form ATP, a reaction that does not require an input of additional energy due to the special environment in the active site of the T state. At the same time a new ADP and P_i bind loosely to the unoccupied O site on β_2 . Step **3**: Proton flux powers another 120° rotation of the γ subunit, consequent conformational changes in the binding sites (L $\rightarrow$ T, O $\rightarrow$ L, T $\rightarrow$ O), and release of ATP from β_3 . Step **4**: Without additional rotation the ADP and P_i in the T site of β_1 form ATP, and additional ADP and P_i bind to the unoccupied O site on β_3 . The process continues with rotation (step **5**) and ATP formation (step **6**) until the cycle is complete, with three ATPs having been produced for every 360° rotation of γ . [Adapted from P. Boyer, 1989, *FASEB J.* **3**:2164; Y. Zhou et al., 1997, *Proc. Nat'l. Acad. Sci. USA* **94**:10583; and M. Yoshida, E. Muneyuki, and T. Hisabori, 2001, *Nat. Rev. Mol. Cell Biol.* **2**:669–677.]

ϵ subunits (see Figure 12-26a). The γ subunit acts as a cam, or nonsymmetrical rotating shaft, whose rotation within the center of the static $(\alpha\beta)_3$ hexamer of F_1 causes it to push sequentially against each of the β subunits and thus cause cyclical changes in their conformations between three different states. As schematically depicted in a view of the bottom of the $(\alpha\beta)_3$ hexamer's globular structure in Figure 12-27, rotation of the γ subunit relative to the fixed $(\alpha\beta)_3$ hexamer causes the nucleotide-binding site of each β subunit to cycle through three conformational states in the following order:

1. An O (open) state that binds ATP very poorly and ADP and P_i weakly
2. An L (loose) state that binds ADP and P_i more strongly but cannot bind ATP
3. A T (tight) state that binds ADP and P_i so tightly that they spontaneously react and form ATP

In the T state the ATP produced is bound so tightly that it cannot readily dissociate from the site—it is trapped until another rotation of the γ subunit returns that β subunit to the O state, thereby releasing ATP and beginning the cycle again. ATP or ADP also binds to regulatory or allosteric sites on the three α subunits; this binding modifies the rate of ATP synthesis according to the level of ATP and ADP in the matrix, but is not directly involved in synthesis of ATP from ADP and P_i .

Several types of evidence support the binding-change mechanism. First, biochemical studies showed that one of the three β subunits on isolated F_1 particles can tightly bind ADP and P_i and then form ATP, which remains tightly bound. The measured ΔG for this reaction is near zero, indicating that once

VIDEO: Rotation of Actin Filament Bound to ATP Synthase

EXPERIMENTAL FIGURE 12-28 The γ subunit of the F_1 complex rotates relative to the $(\alpha\beta)_3$ hexamer. F_1 complexes were engineered that contained β subunits with an additional His-6 sequence, which causes them to adhere to a glass plate coated with a metal reagent that binds polyhistidine. The γ subunit in the engineered F_1 complexes was linked covalently to a fluorescently labeled actin filament. When viewed in a fluorescence microscope, the actin filaments were seen to rotate counterclockwise in discrete 120° steps in the presence of ATP, powered by ATP hydrolysis by the β subunits. [Adapted from H. Noji et al., 1997, *Nature* **386**:299, and R. Yasuda et al., 1998, *Cell* **93**:1117.]

ADP and P_i are bound to the T state of a β subunit, they spontaneously form ATP. Importantly, dissociation of the bound ATP from the β subunit on isolated F_1 particles occurs extremely slowly. This finding suggested that dissociation of ATP would have to be powered by a conformational change in the β subunit, which in turn would be caused by proton movement.

X-ray crystallographic analysis of the $(\alpha\beta)_3$ hexamer yielded a striking conclusion: although the three β subunits are identical in sequence and overall structure, the ADP/ATP-binding sites have different conformations in each subunit. The most reasonable conclusion was that the three β subunits cycle in an energy-dependent reaction between three conformational states (O, L, T), in which the nucleotide-binding site has substantially different structures.

In other studies, intact F_0F_1 complexes were treated with chemical cross-linking agents that covalently linked the γ and ϵ subunits and the c-subunit ring. The observation that such treated complexes could synthesize ATP or use ATP to power proton pumping indicates that the cross-linked proteins normally rotate together.

Finally, rotation of the γ subunit relative to the fixed $(\alpha\beta)_3$ hexamer, as proposed in the binding-change mechanism, was observed directly in the clever experiment depicted in Figure 12-28. In one modification of this experiment in which tiny gold particles, rather than an actin filament, were attached to the γ subunit, rotation rates of 134 revolutions per second were observed. Hydrolysis of three ATPs, which you recall is the reverse reaction catalyzed by the same enzyme, is thought to power one revolution; this result is close to the experimentally determined rate of ATP hydrolysis by F_0F_1 complexes: about 400 ATPs per second. In a related experiment, a γ subunit linked to an ϵ subunit and a ring of c subunits was seen to rotate relative to the fixed $(\alpha\beta)_3$ hexamer. Rotation of the γ subunit in these experiments was powered by ATP hydrolysis, the reverse of the normal process in which proton movement through the F_0 complex drives rotation of the γ subunit.

These observations established that the γ subunit, along with the attached c ring and ϵ subunit, does indeed rotate, thereby driving the conformational changes in the β subunits that are required for binding of ADP and P_i , followed by synthesis and subsequent release of ATP.

Multiple Protons Must Pass Through ATP Synthase to Synthesize One ATP

A simple calculation indicates that the passage of more than one proton is required to synthesize one molecule of ATP from ADP and P_i . Although the ΔG for this reaction under standard conditions is $+7.3$ kcal/mol, at the concentrations of reactants in the mitochondrion, ΔG is probably higher ($+10$ to $+12$ kcal/mol). We can calculate the amount of free energy released by the passage of 1 mol of protons down an electrochemical gradient of 220 mV (0.22 V) from the Nernst equation, setting $n = 1$ and measuring ΔE in volts:

$$\begin{aligned}\Delta G(\text{cal/mol}) &= -nF\Delta E = -(23,062 \text{ cal} \cdot \text{V}^{-1} \cdot \text{mol}^{-1})\Delta E \\ &= (23,062 \text{ cal} \cdot \text{V}^{-1} \cdot \text{mol}^{-1})(0.22 \text{ V}) \\ &= -5074 \text{ cal/mol, or } -5.1 \text{ kcal/mol}\end{aligned}$$

Because the downhill movement of 1 mol of protons releases just over 5 kcal of free energy, the passage of at least two protons is required for synthesis of each molecule of ATP from ADP and P_i .

F_0 c Ring Rotation Is Driven by Protons Flowing Through Transmembrane Channels

Each copy of subunit c contains two membrane-spanning α helices that form a hairpin-like structure. An aspartate residue, Asp-61 (*E. coli* ATPase numbering), in the center of one of these helices in each subunit is thought to play a key role in proton movement by binding and releasing protons as

they traverse the membrane. Chemical modification of this aspartate by the poison dicyclohexylcarbodiimide or its mutation to alanine specifically blocks proton movement through F_0 . According to one current model, the protons traverse the membrane via two staggered, proton half-channels, I and II (see Figure 12-26a and b). They are called half-channels because each only extends halfway across the membrane; the intramembrane termini of the channels are at the level of Asp-61 in the middle of the membrane. Half-channel I is open only to the exoplasmic surface and II is open only to the cytosolic face. Prior to rotation, each of the Asp-61 carboxylate side chains in the c subunits are bound to a proton, except that on the c subunit in contact with half-channel I. The negative charge on that unprotonated carboxylate (the “empty” proton-binding site; see Figure 12-26b, *bottom*) is neutralized by interaction with the positively charged side chain of Arg-210 from the a subunit. Proton translocation across the membrane begins when a proton from the exoplasmic medium moves upwards through half-channel I (Figure 12-26b, step 1). As that proton moves into the empty proton-binding site, it displaces the Arg-210 side chain, which swings toward the filled proton-binding site of the adjacent c subunit in contact with half-channel II (step 2). As a consequence, the positive side chain of Arg-210 displaces the proton bound to Asp-61 of the adjacent c subunit. This displaced proton is now free to travel up half-channel II and out into the cytosolic medium (step 3). Thus, when one proton entering from half-channel I binds to the c ring, a different proton is released to the opposite side of the membrane via half-channel II. Rotation of the entire c ring due to thermal/Brownian motion (step 4) then allows the newly unprotonated c subunit to move into alignment above half-channel I as an adjacent, protonated c subunit rotates in to take its place under half-channel II. The entire cycle is then repeated (step 5), as additional protons move down their electrochemical gradient from the exoplasmic medium to the cytosolic medium. During each partial rotation (360° divided by the number of c subunits in the ring), the c ring rotation is ratcheted in that net movement of the ring only occurs in one direction. The energy driving the protons across the membrane, and thus rotation of the c ring, comes from the electric potential and pH gradient across the membrane. If the direction of proton flow is reversed, which can be done by experimentally reversing the direction of the proton gradient and proton-motive force, the direction of c ring rotation is reversed.

Because the γ subunit of F_1 is tightly attached to the c ring of F_0 , rotation of the c ring associated with proton movement causes rotation of the γ subunit. According to the binding-change mechanism, a 120° rotation of γ powers synthesis of one ATP (see Figure 12-27). Thus complete rotation of the c ring by 360° would generate three ATPs. In *E. coli*, where the F_0 composition is $a_1b_2c_{10}$, movement of 10 protons drives one complete rotation and thus synthesis of three ATPs. This value is consistent with experimental data on proton flux during ATP synthesis, providing indirect support for the model coupling proton movement to c-ring rotation depicted in Figure 12-26. The F_0 from chloroplasts contains 14 c subunits per ring, and movement of 14 protons would be needed for synthesis of three

ATPs. Why these otherwise similar F_0F_1 complexes have evolved to have different H^+ :ATP ratios is not clear.

ATP-ADP Exchange Across the Inner Mitochondrial Membrane Is Powered by the Proton-Motive Force

The proton-motive force is used to power multiple energy-requiring processes in cells. In addition to powering ATP synthesis, the proton-motive force across the inner mitochondrial membrane powers the exchange of ATP formed by oxidative phosphorylation inside the mitochondrion for ADP and P_i in the cytosol. This exchange, which is required to supply ADP and P_i substrate for oxidative phosphorylation to continue, is mediated by two proteins in the inner membrane: a *phosphate transporter* (HPO_4^{2-}/OH^- antiporter) that mediates the import of one HPO_4^{2-} coupled to the export of one OH^- , and an *ATP/ADP antiporter* (Figure 12-29).

The ATP/ADP antiporter allows one molecule of ADP to enter only if one molecule of ATP exits simultaneously. The ATP/ADP antiporter, a dimer of two 30,000-Da subunits, makes up 10–15 percent of the protein in the inner membrane,

FIGURE 12-29 The phosphate and ATP/ADP transport system in the inner mitochondrial membrane. The coordinated action of two antiporters (purple and green) results in the uptake of one ADP^{3-} and one HPO_4^{2-} in exchange for one ATP^{4-} and one hydroxyl, powered by the outward translocation of one proton (mediated by the proteins of the electron transport chain, blue) during electron transport. The outer membrane is not shown here because it is permeable to molecules smaller than 5000 Da.

so it is one of the more abundant mitochondrial proteins. Functioning of the two antiporters together produces an influx of one ADP^{3-} and one P_i^{2-} and efflux of one ATP^{4-} together with one OH^- . Each OH^- transported outward combines with a proton, translocated during electron transport to the intermembrane space, to form H_2O . This drives the overall reaction in the direction of ATP export and ADP and P_i import.

Because some of the protons translocated out of the mitochondrion during electron transport provide the power (by combining with the exported OH^-) for the ATP-ADP exchange, fewer protons are available for ATP synthesis. It is estimated that for every four protons translocated out, three are used to synthesize one ATP molecule and one is used to power the export of ATP from the mitochondrion in exchange for ADP and P_i . This expenditure of energy from the proton concentration gradient to export ATP from the mitochondrion in exchange for ADP and P_i ensures a high ratio of ATP to ADP in the cytosol, where hydrolysis of the high-energy phosphoanhydride bond of ATP is utilized to power many energy-requiring reactions.

 Studies of what turned out to be ATP/ADP antiporter activity were first recorded about 2000 years ago, when Dioscorides (~AD 40–90) described a poisonous herb from the thistle *Atractylis gummifera*, found commonly in the Mediterranean region. The same agent is found in the traditional Zulu multipurpose herbal remedy *impila* (*Callilepis laureola*). In Zulu *impila* means “health,” although it has been associated with numerous poisonings. In 1962 the active agent in the herb, atractyloside, which inhibits the ATP/ADP antiporter, was shown to inhibit oxidative phosphorylation of extramitochondrial ADP but not intramitochondrial ADP. This demonstrated the importance of the ATP/ADP antiporter and has provided a powerful tool to study the mechanism by which this transporter functions.

Dioscorides lived near Tarsus, at the time a province of Rome in southeastern Asia Minor in what is now Turkey. His five-volume *De Materia Medica* (*The Materials of Medicine*) “on the preparation, properties, and testing of drugs” described the medicinal properties of about 1000 natural products and 4740 medicinal usages of them. For approximately 1600 years it was the basic reference in medicine from northern Europe to the Indian Ocean, comparable to today’s *Physicians’ Desk Reference* as a guide for using drugs. ■

Rate of Mitochondrial Oxidation Normally Depends on ADP Levels

If intact isolated mitochondria are provided with NADH (or a source of FADH_2 such as succinate) plus O_2 and P_i , but not ADP, the oxidation of NADH and the reduction of O_2 rapidly cease, because the amount of endogenous ADP is depleted by ATP formation. If ADP is then added, the oxidation of NADH is rapidly restored. Thus mitochondria can oxidize FADH_2 and NADH only as long as there is a source of ADP and P_i to generate ATP. This phenomenon, termed **respiratory control**, occurs because oxidation of NADH and succinate (FADH_2) is obligatorily coupled to proton transport across the inner

mitochondrial membrane. If the resulting proton-motive force is not dissipated during the synthesis of ATP from ADP and P_i (or during other energy-requiring processes), both the transmembrane proton concentration gradient and the membrane electric potential will increase to very high levels. At this point, pumping of additional protons across the inner membrane requires so much energy that it eventually ceases, blocking the coupled oxidation of NADH and other substrates.

Brown-Fat Mitochondria Use the Proton-Motive Force to Generate Heat

Brown-fat tissue, whose color is due to the presence of abundant mitochondria, is specialized for the generation of heat. In contrast, *white-fat tissue* is specialized for the storage of fat and contains relatively few mitochondria.

The inner membrane of brown-fat mitochondria contains *thermogenin*, a protein that functions as a natural **uncoupler** of oxidative phosphorylation and generation of a proton-motive force. Thermogenin, or UCP1, is one of several uncoupling proteins (UCPs) found in most eukaryotes (but not in fermentative yeasts). Thermogenin dissipates the proton-motive force by rendering the inner mitochondrial membrane permeable to protons. As a consequence the energy released by NADH oxidation in the electron transport chain and used to create a proton gradient is not then used to synthesize ATP via ATP synthase. Instead, when protons move back into the matrix down their concentration gradient via thermogenin, the energy is released as heat. Thermogenin is a proton transporter, not a proton channel, and shuttles protons across the membrane at a rate that is a millionfold slower than that of typical ion channels (see Figure 11-2). Thermogenin is similar in sequence to the mitochondrial ATP/ADP transporter, as are many other mitochondrial transporter proteins that compose the ATP/ADP transporter family. Certain small-molecule poisons also function as uncouplers by rendering the inner mitochondrial membrane permeable to protons. One example is the lipid-soluble chemical 2,4-dinitrophenol (DNP), which can reversibly bind to and release protons and shuttle them across the inner membrane from the intermembrane space into the matrix.

Environmental conditions regulate the amount of thermogenin in brown-fat mitochondria. For instance, during the adaptation of rats to cold, the ability of their tissues to generate heat is increased by the induction of thermogenin synthesis. In cold-adapted animals, thermogenin may constitute up to 15 percent of the total protein in the inner mitochondrial membrane.

For many years it was known that small animals and human infants expressed significant amounts of brown fat, but there was scant evidence for it playing a significant role in adult humans. In the newborn human, thermogenesis by brown-fat mitochondria is vital to survival, as it is in hibernating mammals. In fur seals and other animals naturally acclimated to the cold, muscle-cell mitochondria contain thermogenin; as a result, much of the proton-motive force is used for generating heat, thereby maintaining body temperature. Recently investigators have used sophisticated functional imaging methods (for example, positron-emission

tomography) to definitively establish the presence of brown fat in adult humans in the neck, clavicle, and other sites, the levels of which are significantly increased on cold exposure.

KEY CONCEPTS of Section 12.4

Harnessing the Proton-Motive Force to Synthesize ATP

- Peter Mitchell proposed the chemiosmotic hypothesis that a proton-motive force across the inner mitochondrial membrane is the immediate source of energy for ATP synthesis.
- Bacteria, mitochondria, and chloroplasts all use the same chemiosmotic mechanism and a similar ATP synthase to generate ATP (see Figure 12-24).
- ATP synthase (the F_0F_1 complex) catalyzes ATP synthesis as protons flow through the inner mitochondrial membrane (plasma membrane in bacteria) down their electrochemical proton gradient.
- F_0 contains a ring of 10–14 c subunits that is rigidly linked to the rod-shaped γ subunit and the ϵ subunit of F_1 . Together they rotate during ATP synthesis. Resting atop the γ subunit is the hexameric knob of F_1 [$(\alpha\beta)_3$], which protrudes into the mitochondrial matrix (cytosol in bacteria). The three β subunits are the sites of ATP synthesis (see Figure 12-26).
- Movement of protons across the membrane via two half-channels at the interface of the F_0 a subunit and the c ring powers rotation of the c ring with its attached F_1 ϵ and γ subunits.
- Rotation of the F_1 γ subunit, which is inserted in the center of the nonrotating $(\alpha\beta)_3$ hexamer and operates like a camshaft, leads to changes in the conformation of the nucleotide-binding sites in the three F_1 β subunits (see Figure 12-27). By means of this binding-change mechanism, the β subunits bind ADP and P_i , condense them to form ATP, and then release the ATP. Three ATPs are made for each revolution made by the assembly of c, γ , and ϵ subunits.
- The proton-motive force also powers the uptake of P_i and ADP from the cytosol in exchange for mitochondrial ATP and OH^- , thus reducing some of the energy available for ATP synthesis. The ATP/ADP antiporter that participates in this exchange is one of the most abundant proteins in the inner mitochondrial membrane (see Figure 12-29).
- Continued mitochondrial oxidation of NADH and reduction of O_2 are dependent on sufficient ADP being present in the matrix. This phenomenon, termed respiratory control, is an important mechanism for coordinating oxidation and ATP synthesis in mitochondria.
- In brown fat, the inner mitochondrial membrane contains the uncoupler protein thermogenin, a proton transporter that dissipates the proton-motive force into heat. Certain chemicals also function as uncouplers (e.g., DNP) and have the same effect, uncoupling oxidative phosphorylation from electron transport.

12.5 Photosynthesis and Light-Absorbing Pigments

We now shift our attention to photosynthesis, the second main process for synthesizing ATP. In plants, photosynthesis occurs in chloroplasts, large organelles found mainly in leaf cells. During photosynthesis, chloroplasts capture the energy of sunlight, convert it into chemical energy in the form of ATP and NADPH, and then use this energy to make complex carbohydrates out of carbon dioxide and water. The principal carbohydrates produced are polymers of hexose (six-carbon) sugars: sucrose, a glucose-fructose disaccharide (see Figure 2-19), and leaf **starch**, a mixture of two types of a large insoluble glucose polymer called amylose and amylopectin. Starch is the primary storage carbohydrate in plants (Figure 12-30). Leaf starch is synthesized and stored in the chloroplast. Sucrose is synthesized in the leaf cytosol from three-carbon precursors generated in the chloroplast; it is transported to nonphotosynthetic (nongreen) plant tissues (e.g., roots and seeds), which metabolize sucrose for energy by the pathways described in the previous sections. Photosynthesis in plants, as well as in eukaryotic single-celled algae and in several photosynthetic bacteria (e.g., the cyanobacteria and prochlorophytes), also generates oxygen. The overall reaction of oxygen-generating photosynthesis,

is the reverse of the overall reaction by which carbohydrates are oxidized to CO_2 and H_2O . In effect, photosynthesis in chloroplasts produces energy-rich sugars that are broken down and harvested for energy by mitochondria using oxidative phosphorylation.

Although green and purple bacteria also carry out photosynthesis, they use a process that does not generate oxygen. As discussed in Section 12.6, detailed analysis of the photosynthetic system in these bacteria has helped elucidate the first stages in the more common process of oxygen-generating photosynthesis. In this section, we provide an overview of the stages in oxygen-generating photosynthesis and introduce the main molecular components, including the **chlorophylls**, the principal light-absorbing pigments. ■

FIGURE 12-30 Structure of starch. This large glucose polymer and the disaccharide sucrose (see Figure 2-19) are the principal end products of photosynthesis. Both are built of six-carbon sugars (hexoses).

Thylakoid Membranes in Chloroplasts Are the Sites of Photosynthesis in Plants

Chloroplasts are lens shaped with a diameter of approximately 5 μm and a width of approximately 2.5 μm . They contain about 3000 different proteins, 95 percent of which are encoded in the nucleus, made in the cytosol, imported into the organelle, and then transported to their appropriate membrane or space (Chapter 13). They are bounded by two membranes, which do not contain chlorophyll and do not participate directly in the generation of ATP and NADPH driven by light (Figure 12-31). As in mitochondria, the outer membrane of chloroplasts contains porins and thus is permeable to metabolites of small molecular weight. The inner membrane forms a permeability barrier that contains transport proteins for regulating the movement of metabolites into and out of the organelle.

Unlike mitochondria, chloroplasts contain a third membrane—the *thylakoid membrane*—on which the light-driven generation of ATP and NADPH occurs. The chloroplast thylakoid membrane is believed to constitute a single sheet that forms numerous small, interconnected flattened structures, the **thylakoids**, which commonly are arranged in stacks termed *grana* (Figure 12-31). The spaces within all the thylakoids constitute a single continuous compartment, the *thylakoid lumen*. The thylakoid membrane contains a number of integral membrane proteins to which are bound several important prosthetic groups and light-absorbing pigments, most notably chlorophyll. Starch synthesis and storage occurs in the *stroma*, the soluble phase between the thylakoid membrane and the inner membrane. In photosynthetic bacteria extensive invaginations of the plasma membrane form a set of internal membranes, also termed thylakoid membranes, where photosynthesis occurs.

Three of the Four Stages in Photosynthesis Occur Only During Illumination

The photosynthetic process in plants can be divided into four stages (Figure 12-32), each localized to a defined area of the chloroplast: (1) absorption of light, generation of a high-energy electrons, and formation of O_2 from H_2O ; (2) electron transport leading to reduction of NADP^+ to NADPH, and generation of a proton-motive force; (3) synthesis of ATP; and (4) conversion of CO_2 into carbohydrates, commonly referred to as **carbon fixation**. All four stages of photosynthesis are tightly coupled and controlled so as to produce the amount of carbohydrate required by the plant. All the reactions in stages 1–3 are catalyzed by multiprotein complexes in the thylakoid membrane. The generation of a pmf and the use of the pmf to synthesize ATP resemble stages III and IV of mitochondrial oxidative phosphorylation. The enzymes that incorporate CO_2 into chemical intermediates and then convert them to starch are soluble constituents of the chloroplast stroma; the enzymes that form sucrose from three-carbon intermediates are in the cytosol.

Stage 1: Absorption of Light Energy, Generation of High-Energy Electrons, and O_2 Formation The initial step in photosynthesis is the absorption of light by chlorophylls attached

FIGURE 12-31 Cellular structure of a leaf and chloroplast.

Like mitochondria, plant chloroplasts are bounded by a double membrane separated by an intermembrane space. Photosynthesis occurs on a third membrane, the thylakoid membrane, which is surrounded by the inner membrane and forms a series of flattened vesicles (thylakoids) that enclose a single interconnected *luminal* space. The green color of plants is due to the green color of chlorophyll, all of which is localized to the thylakoid membrane. A granum is a stack of adjacent thylakoids. The stroma is the space enclosed by the inner membrane and surrounding the thylakoids. [Photomicrograph courtesy of Katherine Esau, University of California, Davis.]

FIGURE 12-32 Overview of the four stages of photosynthesis. In **stage 1**, light is absorbed by light-harvesting complexes (LHC) and the reaction center of photosystem II (PSII). The LHCs transfer the absorbed energy to the reaction centers, which use it, or the energy absorbed directly from a photon, to oxidize water to molecular oxygen and generate high-energy electrons (electron paths shown by blue arrows). In **stage 2**, these electrons move down an electron transport chain, which uses either lipid-soluble (Q/QH₂) or water-soluble (plastocyanin, PC) electron carriers to shuttle electrons between multiple protein complexes. As electrons move down the chain, they release energy that the complexes use to generate a proton-motive force and, after additional

energy is introduced by absorption of light in photosystem I (PSI), to synthesize the high-energy electron carrier NADPH. In **stage 3**, flow of protons down their concentration and voltage gradient through the F_0F_1 ATP synthase drives ATP synthesis. **Stages 1–3** in plants take place in the thylakoid membrane of the chloroplast. In **stage 4**, in the chloroplast stroma, the energy stored in NADPH and ATP is used to convert CO_2 initially into three-carbon molecules (glyceraldehyde 3-phosphate), a process known as carbon fixation. These molecules are then transported to the cytosol of the cell for conversion to hexose sugars in the form of sucrose. Glyceraldehyde 3-phosphate is also used to make starch within the chloroplast.

to proteins in the thylakoid membranes. Like the heme component of cytochromes, chlorophylls consist of a porphyrin ring attached to a long hydrocarbon side chain (Figure 12-33). In contrast to the hemes (see Figure 12-14), chlorophylls contain a central Mg^{2+} ion (rather than Fe^{2+}) and have an additional five-membered ring. The energy of the absorbed

FIGURE 12-33 Structure of chlorophyll *a*, the principal pigment that traps light energy. Electrons are delocalized among three of chlorophyll *a*'s four central rings (yellow) and the atoms that interconnect them. In chlorophyll, a Mg^{2+} ion, rather than the Fe^{2+} ion found in heme, sits at the center of the porphyrin ring and an additional five-membered ring (blue) is present; otherwise, the structure of chlorophyll is similar to that of heme, found in molecules such as hemoglobin and cytochromes (see Figure 12-14a). The hydro-carbon phytol "tail" facilitates binding of chlorophyll to hydrophobic regions of chlorophyll-binding proteins. The CH_3 group (green) is replaced by a formaldehyde (CHO) group in chlorophyll *b*.

light ultimately is used to remove electrons from a donor (water in the case of green plants), forming oxygen:

The electrons are transferred to a *primary electron acceptor*, a quinone designated Q, which is similar to CoQ in mitochondria. In plants the oxidation of water takes place in a multiprotein complex called *photosystem II (PSII)*.

Stage 2: Electron Transport and Generation of a Proton-Motive Force Electrons move from the quinone primary electron acceptor through a series of electron carriers until they reach the ultimate electron acceptor, usually the oxidized form of **nicotinamide adenine dinucleotide phosphate (NADP⁺)**, reducing it to NADPH. The structure of NADP⁺ is identical to that of NAD⁺ except for the presence of an additional phosphate group. Both molecules gain and lose electrons in the same way (see Figure 2-33). In plants the reduction of NADP⁺ takes place in a complex called *photosystem I (PSI)*. The transport of electrons in the thylakoid membrane is coupled to the movement of protons from the stroma to the thylakoid lumen, forming a pH gradient across the membrane ($\text{pH}_{\text{lumen}} < \text{pH}_{\text{stroma}}$). This process is analogous to generation of a proton-motive force across the inner mitochondrial membrane and in bacterial membranes during electron transport (see Figure 12-23).

Thus the overall reaction of stages 1 and 2 can be summarized as

Stage 3: Synthesis of ATP Protons move down their concentration gradient from the thylakoid lumen to the stroma through the F_0F_1 complex (ATP synthase), which couples proton movement to the synthesis of ATP from ADP and P_i . The chloroplast ATP synthase works similarly to the synthases of mitochondria and bacteria (see Figures 12-26 and 12-27).

Stage 4: Carbon Fixation The NADPH and ATP generated by the second and third stages of photosynthesis provide the energy and the electrons to drive the synthesis of polymers of six-carbon sugars from CO_2 and H_2O . The overall chemical equation is written as

The reactions that generate the ATP and NADPH used in carbon fixation are directly dependent on light energy; thus stages 1–3 are called the *light reactions* of photosynthesis. The reactions in stage 4 are indirectly dependent on light energy; they are sometimes called the *dark reactions* of photosynthesis because they can occur in the dark, utilizing the supplies of ATP and NADPH generated by light energy. However, the reactions in stage 4 are not confined to the dark; in fact, they occur primarily during illumination.

Each Photon of Light Has a Defined Amount of Energy

Quantum mechanics established that light, a form of electromagnetic radiation, has properties of both waves and particles. When light interacts with matter, it behaves as discrete packets of energy (quanta) called *photons*. The energy of a photon, ϵ , is proportional to the frequency of the light wave: $\epsilon = h\gamma$, where h is Planck's constant (1.58×10^{-34} cal · s, or 6.63×10^{-34} J · s) and γ is the frequency of the light wave. It is customary in biology to refer to the wavelength of the light wave, λ , rather than to its frequency, γ . The two are related by the simple equation $\gamma = c \div \lambda$, where c is the velocity of light (3×10^{10} cm/s in a vacuum). Note that photons of *shorter* wavelength have *higher* energies. Also, the energy in 1 mol of photons can be denoted by $E = N\epsilon$, where N is Avogadro's number (6.02×10^{23} molecules or photons/mol). Thus

$$E = N h \gamma = \frac{N h c}{\lambda}$$

The energy of light is considerable, as we can calculate for light with a wavelength of 550 nm (550×10^{-7} cm), typical of sunlight:

$$E = \frac{(6.02 \times 10^{23} \text{ photons/mol})(1.58 \times 10^{-34} \text{ cal} \cdot \text{s})(3 \times 10^{10} \text{ cm/s})}{550 \times 10^{-7} \text{ cm}} = 51,881 \text{ cal/mol}$$

or about 52 kcal/mol. This is enough energy to synthesize several moles of ATP from ADP and P_i if all the energy were used for this purpose.

Photosystems Comprise a Reaction Center and Associated Light-Harvesting Complexes

The absorption of light energy and its conversion into chemical energy occurs in multiprotein complexes called **photosystems**. Found in all photosynthetic organisms, both eukaryotic and prokaryotic, photosystems consist of two closely linked components: a *reaction center*, where the primary events of photosynthesis—generation of high-energy electrons—occur; and an antenna complex consisting of numerous protein complexes, including internal antenna proteins within the photosystem proper and external antenna complexes termed *light-harvesting complexes (LHCs)*, made up of specialized proteins which capture light energy and transmit it to the reaction center (see Figure 12-32).

Both reaction centers and antennas contain tightly bound light-absorbing pigment molecules. Chlorophyll *a* is the principal pigment involved in photosynthesis, being present in both reaction centers and antennas. In addition to chlorophyll *a*, antennas contain other light-absorbing pigments: *chlorophyll b* in vascular plants and *carotenoids* in both plants and photosynthetic bacteria. Carotenoids consist of long branched hydrocarbon chains with alternating single

EXPERIMENTAL FIGURE 12-34 The rate of photosynthesis is greatest at wavelengths of light absorbed by three pigments. The action spectrum of photosynthesis in plants (the ability of light of different wavelengths to support photosynthesis) is shown in black. The energy from light can be converted into ATP only if it can be absorbed by pigments in the chloroplast. Absorption spectra (showing how well light of different wavelengths is absorbed) for three photosynthetic pigments present in the antennas of plant photosystems are shown in color. Comparison of the action spectrum with the individual absorption spectra suggests that photosynthesis at 680 nm is primarily due to light absorbed by chlorophyll *a*; at 650 nm, to light absorbed by chlorophyll *b*; and at shorter wavelengths, to light absorbed by chlorophylls *a* and *b* and by carotenoid pigments, including β -carotene.

and double bonds; they are similar in structure to the visual pigment retinal, which absorbs light in the eye. The presence of various antenna pigments, which absorb light at different wavelengths, greatly extends the range of light that can be absorbed and used for photosynthesis.

One of the strongest pieces of evidence for the involvement of chlorophylls and carotenoids in photosynthesis is that the absorption spectrum of these pigments is similar to the action spectrum of photosynthesis (Figure 12-34). The latter is a measure of the relative ability of light of different wavelengths to support photosynthesis.

When chlorophyll *a* (or any other molecule) absorbs visible light, the absorbed light energy raises electrons in the chlorophyll *a* to a higher-energy (excited) state. This state differs from the ground (unexcited) state largely in the distribution of the electrons around the C and N atoms of the porphyrin ring. Excited states are unstable, and the electrons return to the ground state by one of several competing processes. For chlorophyll *a* molecules dissolved in organic solvents such as ethanol, the principal reactions that dissipate the excited-state energy are the emission of light (fluorescence and phosphorescence) and thermal emission (heat). When the same chloro-

phyll *a* is bound in the unique protein environment of the reaction center, dissipation of excited-state energy occurs by a quite different process that is the key to photosynthesis.

Photoelectron Transport from Energized Reaction-Center Chlorophyll *a* Produces a Charge Separation

The absorption of a photon of light of wavelength ~ 680 nm by one of the two “special-pair” chlorophyll *a* molecules in the reaction center increases the molecules’ energy by 42 kcal/mol (the first excited state). Such an energized chlorophyll *a* molecule in a plant reaction center rapidly donates an electron to an intermediate acceptor, and the electron is rapidly passed on to the primary electron acceptor, quinone Q, near the stromal surface of the thylakoid membrane (Figure 12-35). This light-driven electron transfer, called **photoelectron transport**, depends on the unique environment of both the chlorophylls and the acceptor within the reaction center. Photoelectron transport, which occurs nearly every time a photon is absorbed, leaves a positive charge on the chlorophyll *a* close to the luminal surface of the thylakoid membrane (opposite side from the stroma) and generates a reduced, negatively charged acceptor (Q^-) near the stromal surface.

The Q^- produced by photoelectron transport is a powerful reducing agent with a strong tendency to transfer an electron to another molecule, ultimately to $NADP^+$. The positively charged chlorophyll a^+ , a strong oxidizing agent, attracts an electron from an electron donor on the luminal surface to regenerate the original chlorophyll *a*. In plants, the oxidizing power of four chlorophyll a^+ molecules is used, by way of intermediates, to remove four electrons from $2 H_2O$ molecules bound to a site on the luminal surface to form O_2 :

These potent biological reductants and oxidants provide all the energy needed to drive all subsequent reactions of photosynthesis: electron transport (stage 2), ATP synthesis (stage 3), and CO_2 fixation (stage 4).

Chlorophyll *a* also absorbs light at discrete wavelengths shorter than 680 nm (see Figure 12-34). Such absorption raises the molecule into one of several excited states, whose energies are higher than that of the first excited state described above and which decay by releasing energy within 2×10^{-12} seconds (2 picoseconds, ps) to the lower-energy first excited state with loss of the extra energy as heat. Because photoelectron transport and the resulting charge separation occur only from the first excited state of the reaction-center chlorophyll *a*, the quantum yield—the amount of photosynthesis per absorbed photon—is the same for all wavelengths of visible light shorter (and therefore of higher energy) than 680 nm. How closely the wavelength of light matches the absorption spectra of the pigments determines how likely it is that the photon will be absorbed. Once absorbed, the photon’s exact wavelength is

FIGURE 12-35 Photoelectron transport, the primary event in photosynthesis. After absorption of a photon of light, one of the excited special pair of chlorophyll *a* molecules in the reaction center (left) donates via several intermediates (not shown) an electron to a loosely bound acceptor molecule, the quinone Q, on the stromal surface of the thylakoid membrane, creating an essentially irreversible charge separation across the membrane (right). Subsequent transfers of this electron release energy that is used to generate ATP and NADPH (Figures 12-38 and 12-39). The positively charged chlorophyll a^+ generated when the light-excited electron moves to Q is eventually neutralized by the transfer to the chlorophyll a^+ of another electron. In plants the oxidation of water to molecular oxygen provides this neutralizing electron and takes place in a multiprotein complex called photosystem II (Figure 12-39). The complex photosystem I uses a similar photoelectron transport pathway, but instead of oxidizing water, it receives an electron from a protein carrier called plastocyanin to neutralize the positive charge on chlorophyll a^+ (Figure 12-39).

not critical, provided it is at least energetic enough to push the chlorophyll into the first excited state.

Internal Antenna and Light-Harvesting Complexes Increase the Efficiency of Photosynthesis

Although chlorophyll *a* molecules within a reaction center that are involved directly with charge separation and electron transfer are capable of directly absorbing light and initiating photosynthesis, they most commonly are energized indirectly by energy transferred to them from other light-absorbing and energy-transferring pigments. These other pigments, which include many other chlorophyll molecules, are involved with absorption of photons and passing the energy to the chlorophyll *a* molecules in the reaction center. Some are bound to protein subunits that are considered to be intrinsic components of the photosystem and thus are called internal antennas; others are bound to protein complexes that bind to, but are distinct from, the photosystem core proteins and are called light-harvesting complexes (LHCs). Even at the maximum light intensity encountered by photosynthetic organisms (tropical noontime sunlight), each reaction-center chlorophyll *a* molecule absorbs only about one photon per second, which is not enough to support photosynthesis sufficient for the needs of the plant. The involvement of internal antennas and LHCs greatly increases the efficiency of photosynthesis, especially at more typical light intensities, by increasing absorption of 680-nm light and by extending the range of wavelengths of light that can be absorbed by other antenna pigments.

Photons can be absorbed by any of the pigment molecules in internal antennas or LHCs. The absorbed energy is

then rapidly transferred (in $<10^{-9}$ seconds) to one of the two “special-pair” chlorophyll *a* molecules in the associated reaction center, where it promotes the primary photosynthetic charge separation (Figure 12-35). Photosystem core proteins and LHC proteins maintain the pigment molecules in the precise orientation and position optimal for light absorption and energy transfer, thereby maximizing the very rapid and efficient *resonance transfer* of energy from antenna pigments to reaction-center chlorophylls. Resonance energy transfer does not involve the transfer of an electron. Studies on one of the two photosystems in cyanobacteria, which are similar to those in multicellular, seed-bearing plants, suggest that energy from absorbed light is funneled first to a “bridging” chlorophyll in each LHC and then to the special pair of reaction-center chlorophylls (Figure 12-36a). Surprisingly, however, the molecular structures of LHCs from plants and cyanobacteria are completely different from those in green and purple bacteria, even though both types contain carotenoids and chlorophylls in a clustered arrangement within the membrane. Figure 12-36b shows the distribution of the chlorophyll pigments in photosystem I from *Pisum sativum* (garden pea) together with those from peripheral LHC antennas. The large number of internal and LHC antenna chlorophylls surround the core reaction center to permit efficient transfer of absorbed light energy to the special chlorophylls in the reaction center.

Although LHC antenna chlorophylls can transfer light energy absorbed from a photon, they cannot release an electron. As we’ve seen already, this function resides in the two reaction-center chlorophylls. To understand their electron-releasing ability, we examine the structure and function of the reaction center in bacterial and plant photosystems in the next section.

FIGURE 12-36 Light-harvesting complexes and photosystems in cyanobacteria and plants. (a) Diagram of the membrane of a cyanobacterium, in which the multiprotein light-harvesting complex (LHC) contains 90 chlorophyll molecules (green) and 31 other small molecules, all held in a specific geometric arrangement for optimal light absorption and energy transfer. Of the six chlorophyll molecules in the reaction center, two constitute the special-pair chlorophylls (ovals, dark green) that can initiate photoelectron transport when excited (blue arrow). Resonance transfer of energy (red arrows) rapidly funnels energy from absorbed light to one of two “bridging”

chlorophylls (squares, dark green) and thence to chlorophylls in the reaction center. (b) Three-dimensional organization of the photosystem I (PSI) and associated LHCs of *Pisum sativum* (garden pea), as determined by x-ray crystallography and seen from the plane of the membrane. Only the chlorophylls together with the reaction-center electron carriers are shown. (c) Expanded view of the reaction center from (b), rotated 90° about a vertical axis. [Part (a) adapted from W. Kühlbrandt, 2001, *Nature* **411**:896, and P. Jordan et al., 2001, *Nature* **411**:909. Parts (b) and (c) based on the structural determination by A. Ben-Sham et al., 2003, *Nature* **426**:630.]

KEY CONCEPTS of Section 12.5

Photosynthesis and Light-Absorbing Pigments

- The principal end products of photosynthesis in plants are molecular oxygen and polymers of six-carbon sugars (starch and sucrose).
- The light-capturing and ATP-generating reactions of photosynthesis occur in the thylakoid membrane located within chloroplasts. The permeable outer membrane and inner membrane surrounding chloroplasts do not participate directly in photosynthesis (see Figure 12-31).
- There are four stages in photosynthesis: (1) absorption of light, generation of a high-energy electrons, and formation of O_2 from H_2O ; (2) electron transport leading to reduction of $NADP^+$ to NADPH, and to generation of a proton-motive force; (3) synthesis of ATP; and (4) conversion of CO_2 into carbohydrates (carbon fixation).
- In stage 1 of photosynthesis, light energy is absorbed by one of two “special-pair” chlorophyll *a* molecules bound to

reaction-center proteins in the thylakoid membrane. The energized chlorophylls donate, via intermediates, an electron to a quinone on the opposite side of the membrane, creating a charge separation (see Figure 12-35). In green plants, the positively charged chlorophylls then remove electrons from water, forming molecular oxygen (O_2).

- In stage 2, electrons are transported from the reduced quinone via carriers in the thylakoid membrane until they reach the ultimate electron acceptor, usually $NADP^+$, reducing it to NADPH. Electron transport is coupled to movement of protons across the membrane from the stroma to the thylakoid lumen, forming a pH gradient (proton-motive force) across the thylakoid membrane.
- In stage 3, movement of protons down their electrochemical gradient through F_0F_1 complexes (ATP synthase) powers the synthesis of ATP from ADP and P_i .
- In stage 4, the NADPH and ATP generated in stages 2 and 3 provide the energy and the electrons to drive the fixation

of CO₂, which results in the synthesis of carbohydrates. These reactions occur in the thylakoid stroma and cytosol.

- Associated with each reaction center are multiple internal antenna and light-harvesting complexes (LHCs), which contain chlorophylls *a* and *b*, carotenoids, and other pigments that absorb light at multiple wavelengths. Energy, but not an electron, is transferred from the internal antenna and LHC chlorophyll molecules to reaction-center chlorophylls by resonance energy transfer (see Figure 12-36).

12.6 Molecular Analysis of Photosystems

As noted in the previous section, photosynthesis in the green and purple bacteria does not generate oxygen, whereas photosynthesis in cyanobacteria, algae, and plants does.* This difference is attributable to the presence of two types of photosystem (PS) in the latter organisms: PSI reduces NADP⁺ to NADPH, and PSII forms O₂ from H₂O. In contrast, the green and purple bacteria have only one type of photosystem, which cannot form O₂. We first discuss the simpler photosystem of purple bacteria and then consider the more complicated photosynthetic machinery in chloroplasts.

The Single Photosystem of Purple Bacteria Generates a Proton-Motive Force but No O₂

The three-dimensional structures of photosynthetic reaction centers have been determined, permitting scientists to trace in detail the paths of electrons during and after the absorption of light. The reaction center of purple bacteria contains three protein subunits (L, M, and H) located in the plasma membrane (Figure 12-37). Bound to these proteins are the prosthetic groups that absorb light and transport electrons during photosynthesis. The prosthetic groups include a “special pair” of bacteriochlorophyll *a* molecules equivalent to the reaction-center chlorophyll *a* molecules in plants, as well as several other pigments and two quinones, termed Q_A and Q_B, that are structurally similar to mitochondrial ubiquinone.

Initial Charge Separation The mechanism of charge separation in the photosystem of purple bacteria is identical to that in plants outlined earlier; that is, energy from absorbed light is used to strip an electron from a reaction-center bacteriochlorophyll *a* molecule and transfer it, via several different pigments, to the primary electron acceptor Q_B, which is loosely bound to a site on the cytosolic membrane face. The

*A very different type of mechanism used to harvest the energy of light, which occurs only in certain archaeobacteria, is not discussed here because it is very different from reaction center mechanisms described here. In this other mechanism, the plasma-membrane protein that absorbs a photon of light, called bacteriorhodopsin, also pumps one proton from the cytosol to the extracellular space for every photon of light absorbed.

FIGURE 12-37 Three-dimensional structure of the photosynthetic reaction center from the purple bacterium *Rhodospirillum rubrum*. (Top) The L subunit (yellow) and M subunit (gray) each form five transmembrane α helices and have a very similar structure overall; the H subunit (light blue) is anchored to the membrane by a single transmembrane α helix. A fourth subunit (not shown) is a peripheral protein that binds to the exoplasmic segments of the other subunits. (Bottom) Within each reaction center, but not easily distinguished in the top image, is a special pair of bacteriochlorophyll *a* molecules (green), capable of initiating photoelectron transport; two accessory chlorophylls (purple); two pheophytins (dark blue), and two quinones, Q_A and Q_B (orange). Q_B is the primary electron acceptor during photosynthesis. [After M. H. Stowell et al., 1997, *Science* 276:812.]

chlorophyll thereby acquires a positive charge, and Q_B acquires a negative charge. To determine the pathway traversed by electrons through the bacterial reaction center, researchers exploited the fact that each pigment absorbs light of only certain wavelengths, and its absorption spectrum changes when it possesses an extra electron. Because these electron movements are completed in less than 1 millisecond (ms), a special technique called *picosecond absorption spectroscopy* is required to monitor the changes in the absorption spectra of the various pigments as a function of time shortly after the absorption of a light photon.

When a preparation of bacterial membrane vesicles is exposed to an intense pulse of laser light lasting less than 1 ps, each reaction center absorbs one photon (Figure 12-38). Light absorbed by the chlorophyll *a* molecules in each reaction center

FIGURE 12-38 Cyclic electron flow in the single photosystem of purple bacteria. Cyclic electron flow generates a proton-motive force but no O_2 . Blue arrows indicate flow of electrons; red arrows indicate proton movement. (Left) Energy absorbed directly from light or funneled from an associated LHC (not illustrated here) energizes one of the special-pair chlorophylls in the reaction center. Photoelectron transport from the energized chlorophyll, via an accessory chlorophyll, pheophytin (Ph), and quinone A (Q_A), to quinone B (Q_B) forms the semiquinone $Q^{\cdot-}$ and leaves a positive charge on the chlorophyll. Following absorption of a second photon and transfer of a second electron to the semiquinone, the quinone rapidly picks up two protons from the

cytosol to form QH_2 . (Center) After diffusing through the membrane and binding to the Q_0 site on the exoplasmic face of the cytochrome bc_1 complex, QH_2 donates two electrons and simultaneously gives up two protons to the external medium in the periplasmic space, generating a proton electrochemical gradient (proton-motive force). Electrons are transported back to the reaction-center chlorophyll via a soluble cytochrome, which diffuses in the periplasmic space. Note the cyclic path (blue) of electrons. Operation of a Q cycle in the cytochrome bc_1 complex pumps additional protons across the membrane to the external medium, as in mitochondria. [Adapted from J. Deisenhofer and H. Michaeli, 1991, *Ann. Rev. Cell Biol.* 7:1.]

converts them to the excited state, and the subsequent electron transfer processes are synchronized in all reaction centers in the experimental sample. Within 4×10^{-12} seconds (4 ps), an electron moves, via the accessory bacterial chlorophyll (see Figure 12-37, bottom) as an intermediate, to the pheophytin molecules (Ph), leaving a positive charge on the chlorophyll a . This state exists for about 200 ps before the electron moves to Q_A , and then, in the slowest step, it takes $\sim 200 \mu s$ for it to move to Q_B . This pathway of electron flow is traced in the left part of Figure 12-38. The later steps are slower than inherently rapid electron movements because they involve relatively slow protein conformational changes.

Subsequent Electron Flow and Coupled Proton Movement After the primary electron acceptor, Q_B , in the bacterial reaction center accepts one electron, forming $Q_B^{\cdot-}$, it accepts a second electron from the same reaction-center chlorophyll following its re-excitation (e.g., by absorption of a second photon or transfer of energy from antenna molecules). The quinone then binds two protons from the cytosol, forming the reduced quinone (QH_2), which is released from the reaction center (Figure 12-38). QH_2 diffuses within the bacterial membrane to the Q_0 site on the exoplasmic face of a cytochrome bc_1 electron transport complex similar in structure to complex III in mitochondria. There it releases its

two protons into the periplasmic space (the space between the plasma membrane and the bacterial cell wall). This process moves protons from the cytosol to the outside of the cell, generating a proton-motive force across the plasma membrane. Simultaneously, QH_2 releases its two electrons, which move through the cytochrome bc_1 complex exactly as depicted for the mitochondrial complex III (Co QH_2 -cytochrome c reductase) in Figure 12-18. The Q cycle in the bacterial reaction center, like the Q cycle in mitochondria, pumps additional protons from the cytosol to the intermembrane space, thereby increasing the proton-motive force.

The acceptor for electrons transferred through the cytochrome bc_1 complex is a soluble cytochrome, a one-electron carrier, in the periplasmic space, which is reduced from the Fe^{3+} to the Fe^{2+} state. The reduced cytochrome (analogous to cytochrome c in mitochondria) then diffuses to a reaction center, where it releases its electron to a positively charged chlorophyll a^+ , returning that chlorophyll to the uncharged ground state and the cytochrome to the Fe^{3+} state. This *cyclic* electron flow generates no oxygen and no reduced coenzymes, but it has generated a proton-motive force.

As in other systems, this proton-motive force is used by the F_0F_1 complex located in the bacterial plasma membrane to synthesize ATP and also to transport molecules across the membrane against a concentration gradient.

Chloroplasts Contain Two Functionally and Spatially Distinct Photosystems

In the 1940s, biophysicist R. Emerson discovered that the rate of plant photosynthesis generated by light of wavelength 700 nm can be greatly enhanced by adding light of shorter wavelength (higher energy). He found that a combination of light at, say, 600 and 700 nm supports a greater rate of photosynthesis than the sum of the rates for the two separate wavelengths. This so-called *Emerson effect* led researchers to conclude that photosynthesis in plants involves the interaction of two separate photosystems, referred to as *PSI* and *PSII*. PSI is driven by light of wavelength 700 nm or less; PSII, only by shorter-wavelength light (<680 nm).

In chloroplasts, the special-pair reaction-center chlorophylls that initiate photoelectron transport in PSI and PSII differ in their light-absorption maxima because of differences in their protein environments. For this reason, these chlorophylls are often denoted P_{680} (PSII) and P_{700} (PSI). Like a bacterial reaction center, each chloroplast reaction center is associated with multiple internal antenna and light-harvesting complexes (LHCs); the LHCs associated with PSII (e.g., LHCII) and PSI (e.g., LHCI) contain different proteins.

The two photosystems also are distributed differently in thylakoid membranes: PSII primarily in stacked regions (grana, see Figure 12-31) and PSI primarily in unstacked regions. The stacking of the thylakoid membranes may be due to the binding properties of the proteins associated with

PSII, especially LHCII. Evidence for this distribution came from studies in which thylakoid membranes were gently fragmented into vesicles by ultrasound. Stacked and unstacked thylakoid vesicles were then fractionated by density-gradient centrifugation. The stacked fractions contained primarily PSII protein and the unstacked fractions PSI.

Finally, and most importantly, the two chloroplast photosystems differ significantly in their functions (Figure 12-39): only PSII oxidizes water to form molecular oxygen, whereas only PSI transfers electrons to the final electron acceptor, NADP^+ . Photosynthesis in chloroplasts can follow a linear or cyclic pathway. The linear pathway, which we discuss first, can support carbon fixation as well as ATP synthesis. In contrast, the cyclic pathway supports only ATP synthesis and generates no reduced NADPH for use in carbon fixation. Photosynthetic algae and cyanobacteria contain two photosystems analogous to those in chloroplasts. Similar proteins and pigments compose photosystems I and II of plants and photosynthetic bacteria.

Linear Electron Flow Through Both Plant Photosystems, PSII and PSI, Generates a Proton-Motive Force, O_2 , and NADPH

Linear electron flow in chloroplasts involves PSII and PSI in an obligate series in which electrons are transferred from H_2O to NADP^+ . The process begins with absorption of a

FIGURE 12-39 Linear electron flow in plants, which requires both chloroplast photosystems PSI and PSII. Blue arrows indicate flow of electrons; red arrows indicate proton movement. LHCs are not shown. (Left) In the PSII reaction center, two sequential light-induced excitations of the same P_{680} chlorophylls result in reduction of the primary electron acceptor Q_B to QH_2 . On the luminal side of PSII, electrons removed from H_2O in the thylakoid lumen are transferred to P_{680}^+ , restoring the reaction-center chlorophylls to the ground state and generating O_2 . (Center) The cytochrome *bf* complex then accepts electrons from QH_2 , coupled to the release of two protons into the lumen. Operation of a Q cycle in the cytochrome *bf* complex translocates

additional protons across the membrane to the thylakoid lumen, increasing the proton-motive force. (Right) In the PSI reaction center, each electron released from light-excited P_{700} chlorophylls moves via a series of carriers in the reaction center to the stromal surface, where soluble ferredoxin (an Fe-S protein) transfers the electron to ferredoxin-NADP⁺ reductase (FNR). This enzyme uses the prosthetic group flavin adenine dinucleotide (FAD) and a proton to reduce NADP^+ , forming NADPH. P_{700}^+ is restored to its ground state by addition of an electron carried from PSII via the cytochrome *bf* complex and plastocyanin, a soluble electron carrier.

photon by PSII, causing an electron to move from a P_{680} chlorophyll *a* to an acceptor plastoquinone (Q_B) on the stromal surface (Figure 12-39). The resulting oxidized P_{680}^+ strips one electron from the relatively unwilling donor H_2O , forming an intermediate in O_2 formation and a proton, which remains in the thylakoid lumen and contributes to the proton-motive force. After P_{680} absorbs a second photon, the semiquinone $Q^{\bullet-}$ accepts a second electron and picks up two protons from the stromal space, generating QH_2 . After diffusing in the membrane, QH_2 binds to the Q_o site on a cytochrome *bf* complex that is analogous to the bacterial cytochrome *bc_1* complex and to the mitochondrial complex III. As in these systems, a Q cycle operates, thereby increasing the proton-motive force generated by electron transport. After the cytochrome *bf* complex accepts electrons from QH_2 , it transfers them, one at a time, to the Cu^{2+} form of the soluble electron carrier plastocyanin (analogous to cytochrome *c*), reducing it to the Cu^{1+} form. Reduced plastocyanin then diffuses in the thylakoid lumen, carrying the electron to PSI.

Absorption of a photon by PSI leads to removal of an electron from the reaction-center chlorophyll *a*, P_{700} (Figure 12-39). The resulting oxidized P_{700}^+ is reduced by an electron passed from the PSII reaction center via the cytochrome *bf* complex and plastocyanin. Again, this is analogous to the situation in mitochondria, where cytochrome *c* acts as a single-electron shuttle from complex III to complex IV (see Figure 12-16). The electron taken up at the luminal surface by the P_{700} energized by photon absorption moves within PSI via several carriers to the stromal surface of the thylakoid membrane, where it is accepted by ferredoxin, an iron-sulfur (Fe-S) protein. In linear electron flow electrons excited in PSI are transferred from ferredoxin via the enzyme ferredoxin-NADP⁺ reductase (FNR). This enzyme uses the prosthetic group FAD as an electron carrier to reduce NADP⁺, forming, together with one proton picked up from the stroma, the reduced molecule NADPH.

F_0F_1 complexes in the thylakoid membrane use the proton-motive force generated during linear electron flow to synthesize ATP on the stromal side of the membrane. Thus this pathway exploits the energy from multiple photons absorbed by both PSII and PSI and their antennas to generate both NADPH and ATP in the stroma of the chloroplast, where they are utilized for CO_2 fixation.

An Oxygen-Evolving Complex Is Located on the Luminal Surface of the PSII Reaction Center

Somewhat surprisingly, the structure of the PSII reaction center, which removes electrons from H_2O to form O_2 , resembles that of the reaction center of photosynthetic purple bacteria, which does not form O_2 . Like the bacterial reaction center, the PSII reaction center contains two molecules of chlorophyll *a* (P_{680}), as well as two other accessory chlorophylls, two pheophytins, two quinones (Q_A and Q_B), and one nonheme iron atom. These small molecules are bound to

FIGURE 12-40 Electron flow and O_2 evolution in chloroplast PSII.

The PSII reaction center, comprising the two integral proteins D1 and D2, special-pair chlorophylls (P_{680}), and other electron carriers, is associated with an oxygen-evolving complex on the luminal surface. Bound to the three extrinsic proteins (33, 23, and 17 kDa) of the oxygen-evolving complex are four manganese ions (Mn, red), a Ca^{2+} ion (blue), and a Cl^- ion (yellow). These bound ions function in the splitting of H_2O and maintain the environment essential for high rates of O_2 evolution. Tyrosine-161 (Y161) of the D1 polypeptide conducts electrons from the Mn ions to the oxidized reaction-center chlorophyll (P_{680}^+), reducing it to the ground state P_{680} . [Adapted from C. Hoganson and G. Babcock, 1997, *Science* 277:1953.]

two proteins in PSII, called D1 and D2, whose sequences are remarkably similar to the sequences of the L and M subunits of the bacterial reaction center (Figure 12-37), attesting to their common evolutionary origins. When PSII absorbs a photon with a wavelength of <680 nm, it triggers the loss of an electron from a P_{680} molecule, generating P_{680}^+ . As in photosynthetic purple bacteria, the electron is transported rapidly, probably via an accessory chlorophyll, to a pheophytin, then to a quinone (Q_A), and then to the primary electron acceptor, Q_B , on the outer (stromal) surface of the thylakoid membrane (Figures 12-39 and 12-40).

The photochemically oxidized reaction-center chlorophyll of PSII, P_{680}^+ , is the *strongest* biological oxidant known. The reduction potential of P_{680}^+ is more positive than that of water, and thus it can oxidize water to generate O_2 and H^+ ions. Photosynthetic bacteria cannot oxidize water because the excited chlorophyll a^+ in the bacterial reaction center is not a sufficiently strong oxidant. Thus they use other sources of electrons, such as H_2S and H_2 .

The oxidation of H_2O , which provides the electrons for reduction of P_{680}^+ in PSII, is catalyzed by a three-protein complex, the *oxygen-evolving complex*, located on the luminal surface of PSII in the thylakoid membrane. The oxygen-evolving complex contains four manganese (Mn) ions connected by bridging oxygen atoms, as well as bound Cl^- and

EXPERIMENTAL FIGURE 12-41 A single PSII absorbs a photon and transfers an electron four times to generate one O₂. Dark-adapted chloroplasts were exposed to a series of closely spaced, short (5 μ s) pulses of light that activated virtually all the PSIIs in the preparation. The peaks in O₂ evolution occurred after every fourth pulse, indicating that absorption of four photons by one PSII is required to generate each O₂ molecule. Because the dark-adapted chloroplasts were initially in a partially reduced state, the peaks in O₂ evolution occurred after flashes 3, 7, and 11. [From J. Berg et al., 2002, *Biochemistry*, 5th ed., W. H. Freeman and Company.]

Ca²⁺ ions (Figure 12-40); this is one of the very few cases in which manganese plays a role in a biological system. These manganese ions together with the three extrinsic proteins can be removed from the reaction center by treatment with solutions of concentrated salts; this abolishes O₂ formation but does not affect light absorption or the initial stages of electron transport.

The oxidation of two molecules of H₂O to form O₂ requires the removal of four electrons, but absorption of each photon by PSII results in the transfer of just one electron. A simple experiment, described in Figure 12-41, resolved whether the formation of O₂ depends on a single PSII or multiple ones acting in concert. The results indicated that a single PSII must lose an electron and then oxidize the oxygen-evolving complex four times in a row for an O₂ molecule to be formed.

Manganese is known to exist in multiple oxidation states with from two to five positive charges. Indeed, spectroscopic studies showed that the bound Mn ions in the oxygen-evolving complex cycle through five different oxidation states, S₀–S₄. In this S cycle, a total of two H₂O molecules are split to generate four protons, four electrons, and one O₂ molecule. Channels in the structure of the oxygen-evolving complex have been proposed to serve as conduits for the delivery of H₂O to and the removal of O₂ from the active site through the surrounding protein of the oxygen-evolving complex. The electrons released from H₂O are transferred, one at a time, via the Mn ions and a nearby tyrosine side chain on the D1 subunit to the reaction-center P₆₈₀⁺, where they regenerate the reduced chlorophyll, P₆₈₀, ground state by replacing the electron that was removed by light absorption. The protons released from H₂O remain in the thylakoid lumen.

Herbicides that inhibit photosynthesis not only are very important in agriculture but also have proved useful in dissecting the pathway of photoelectron transport in plants. One such class of herbicides, the *s*-triazines (e.g., atrazine), binds specifically to the D1 subunit in the PSII reaction center, thus inhibiting binding of oxidized Q_B to its site on the stromal surface of the thylakoid membrane. When added to illuminated chloroplasts, *s*-triazines cause all downstream electron carriers to accumulate in the oxidized form, because no electrons can be released from PSII. In atrazine-resistant mutants, a single amino acid change in D1 renders it unable to bind the herbicide, so photosynthesis proceeds at normal rates. Such resistant weeds are prevalent and present a major agricultural problem. ■

Multiple Mechanisms Protect Cells Against Damage from Reactive Oxygen Species During Photoelectron Transport

As we saw earlier in the case of mitochondria, ROS generated during electron transport through the electron transport chain (see Figure 12-21) can both serve as signals to regulate organelle function and cause damage to a variety of biomolecules. The same is true for chloroplasts. Even though the PSI and PSII photosystems with their associated light-harvesting complexes are remarkably efficient at converting radiant energy to useful chemical energy in the form of ATP and NADPH, they are not perfect. Depending on the intensity of the light and the physiologic conditions of the cells, a relatively small—but significant—amount of energy absorbed by chlorophylls in the light-harvesting antennas and reaction centers results in the chlorophyll being converted to an activated state called “triplet” chlorophyll. In this state, the chlorophyll can transfer some of its energy to molecular oxygen (O₂), converting it from its normal, *relatively* unreactive ground state, called triplet oxygen (³O₂), to a very highly reactive (ROS) singlet state form, ¹O₂. Some of this ¹O₂ can be used for signaling to the nucleus to communicate the metabolic state of the chloroplast to the rest of the cell. However, if the majority of the ¹O₂ is not quickly quenched by reacting with specialized ¹O₂ “scavenger molecules,” it will react with and usually damage nearby molecules. This damage can suppress the efficiency of thylakoid activity and is called *photoinhibition*. Carotenoids (polymers of unsaturated isoprene groups, including beta-carotene, which gives carrots their orange color) and α -tocopherol (a form of vitamin E) are hydrophobic small molecules that play important roles as ¹O₂ quenchers to protect plants. For example, inhibition of tocopherol synthesis in the unicellular green alga *Chlamydomonas reinhardtii* by the herbicide pyrazolynate can result in greater light-induced photoinhibition. The carotenoids, which very efficiently siphon off energy from the dangerous triplet chlorophyll when they are in close proximity, are the quantitatively most important molecules for preventing ¹O₂ formation. There are about 11 carotenoid molecules and 35 chlorophylls in the PSII monomer from the cyanobacterium *Thermosynechococcus elongatus*.

EXPERIMENTAL FIGURE 12-42 The chaperone HSP70B helps PSII recover from photoinhibition after exposure to intense light. The unicellular green alga *Chlamydomonas reinhardtii* was genetically manipulated so that it had abnormally high or low levels of the chaperone protein HSP70B. The high, low, and normal strains were then exposed to high-intensity light ($2400 \mu\text{E m}^{-2} \text{s}^{-1}$) for 60 minutes to induce photoinhibition followed by exposure to low light ($20 \mu\text{E m}^{-2} \text{s}^{-1}$) for up to 150 minutes. The effects of photoinhibition by the high-intensity light and the ability of PSII to recover from the photoinhibition were measured using fluorescence spectroscopy to determine PSII activity. The ability of the cells to recover PSII activity depends on the levels of HSP70B—the more HSP70B available, the more rapid the recovery—due to HSP70B protection of the PSII reaction centers that had withstood $^1\text{O}_2$ -induced D1 subunit damage. [From Schroda et al., 1999, *Plant Cell* 11:1165.]

Under intense illumination, photosystem PSII is especially prone to generating $^1\text{O}_2$, whereas PSI will produce other ROS, including superoxide, hydrogen peroxide, and hydroxyl radicals. The D1 subunit in the PSII reaction center (see Figure 12-40) is, even under low light conditions, subjected to almost constant $^1\text{O}_2$ -mediated damage. A damaged reaction center moves from the grana to the unstacked regions of the thylakoid, where the D1 subunit is degraded by

a protease and replaced by newly synthesized D1 protein in what is called the D1 protein damage-repair cycle. The rapid replacement of damaged D1, which requires a high rate of D1 synthesis, helps the PSII recover from photoinactivation and maintain sufficient activity. The experiment in Figure 12-42 shows that an important component in the damage-repair cycle is the chaperone protein HSP70B (see Chapter 3), which binds to the damaged PSII and helps prevent loss of the other components of the complex as the D1 subunit is replaced. The extent of photoinhibition can depend on the amount of HSP70B available to the chloroplasts.

Cyclic Electron Flow Through PSI Generates a Proton-Motive Force but No NADPH or O_2

As we've seen, electrons from reduced ferredoxin in PSI are transferred to NADP^+ during linear electron flow, resulting in production of NADPH (see Figure 12-39). In some circumstances, such as drought, high light intensity, or low carbon dioxide levels, cells must generate relatively greater amounts of ATP relative to NADPH than that produced by linear electron flow. To do this, they photosynthetically produce ATP from PSI without concomitant NADPH production. This is accomplished using a PSII-independent process called *cyclic photophosphorylation*, or *cyclic electron flow*. In this process electrons cycle between PSI, ferredoxin, plastoquinone (Q), and the cytochrome *bf* complex (Figure 12-43); thus no *net* NADPH is generated, and there is no need to oxidize water and produce O_2 . There are two distinct cyclic electron flow pathways: the *NAD(P)H dehydrogenase (Ndh)-dependent* (shown in Figure 12-43) and *Ndh-independent* pathways. Ndh is an enzyme complex, very similar to the mitochondrial complex I (see Figure 12-16), that oxidizes NADPH or NADH while reducing Q to QH_2 and thus contributes to the proton motive force by transporting protons. During cyclic electron flow, the substrate for the Ndh is the NADPH generated by light absorption by PSI, ferredoxin, and ferredoxin-NADP reductase (FNR). The QH_2 formed by Ndh then diffuses through the thylakoid membrane to the Q_0 binding site on the luminal surface of the cytochrome *bf* complex. There it releases two electrons to the cytochrome *bf* complex and two protons to the thylakoid lumen, generating a proton-motive force. As in linear electron flow, these electrons return to PSI via plastocyanin. This cyclic electron flow is similar to the cyclic process that occurs in the single photosystem of purple bacteria (see Figure 12-38). A Q cycle operates in the cytochrome *bf* complex during cyclic electron flow, leading to transport of two additional protons into the lumen for each pair of electrons transported and a greater proton-motive force.

In Ndh-independent cyclic electron flow, the mechanism of which has not yet been completely defined, electrons from the ferredoxin are used to reduce Q, either via a hypothetical membrane-associated ferredoxin:plastoquinone oxidoreductase (FQR) or via the Q_i site, which is part of the Q cycle in the cytochrome *bf* complex. Genetic analysis of *Arabidopsis thaliana* has identified several genes involved in

FIGURE 12-43 Cyclic electron flow in plants, which generates a proton-motive force and ATP but no oxygen or net NADPH. In the NAD(P)H-dehydrogenase (Ndh)-dependent pathway for cyclic electron flow, light energy is used by PSI to transport electrons in a cycle to generate a proton-motive force and ATP without oxidizing water. The NADPH formed via the PSI/ferredoxin/FNR—instead of being used to

fix carbon—is oxidized by Ndh. The released electrons are transferred to plastoquinone (Q) within the membrane to generate QH₂, which then transfers the electrons to the cytochrome *bf* complex, then to plastocyanin, and finally back to PSI, as is the case for the linear electron flow pathway (see Figure 12-39).

Ndh-independent cyclic electron flow, including the integral membrane protein PGRL1.

Relative Activities of Photosystems I and II Are Regulated

In order for PSII, which is preferentially located in the stacked grana, and PSI, which is preferentially located in the unstacked thylakoid membranes, to act in sequence during linear electron flow, the amount of light energy delivered to the two reaction centers must be controlled so that each center activates the same number of electrons. This balanced condition is called state 1 (Figure 12-44a). If the two photosystems are not equally excited, then cyclic electron flow occurs in PSI and PSII becomes less active (state 2). Variations in the wavelengths and intensities of ambient light (as a consequence of the time of day, cloudiness, etc.) can change the relative activation of the two photosystems, potentially upsetting the appropriate relative amounts of linear and cyclic electron flow necessary for production of optimal ratios of ATP and NADPH.

One mechanism for regulating the relative contributions of PSI and PSII, in response to varying lighting conditions and thus the relative amounts of linear and cyclic electron flow, entails redistributing the light-harvesting complex LHCII between the two photosystems. The more LHCII associated with a particular photosystem, the more efficiently that system will be activated by light and the greater its contribution to electron flow. The distribution of LHCII between PSI and PSII is mediated by reversible phosphorylation and dephosphorylation of LHCII by a regulated, membrane-

associated kinase and an apparently constitutively active phosphatase. LHCII's unphosphorylated form is preferentially associated with PSII, and the phosphorylated form diffuses in the thylakoid membrane from the grana to the unstacked region and associates with PSI more than the unphosphorylated form. Light conditions in which there is preferential absorption of light by PSII result in the production of high levels of QH₂ that bind to the cytochrome *bf* complex (see Figure 12-39). Consequent conformational changes in this complex are apparently responsible for activation of the LHCII kinase, increased LHCII phosphorylation, compensatory increased activation of PSI relative to PSII, and thus an increase in cyclic electron flow in state 2 (Figure 12-44a). When the green alga *Chlamydomonas reinhardtii* was forced into state 2, it was possible to isolate a “super-supercomplex” containing PSI, LHCI, LHCII, Cyt *bf*, ferredoxin (Fd), NADPH oxidoreductase (FNR), and the integral membrane protein PGRL1 that participates in *Ndh*-independent cyclic electron flow (Figure 12-44b). Thus it appears that the efficient operation of electron transport chains has involved the evolution of functional complexes of increasing size and complexity, from individual proteins to complexes to supercomplexes to super-supercomplexes.

Regulating the supramolecular organization of the photosystems in plants has the effect of directing them toward ATP production (state 2) or toward generation of reducing equivalents (NADPH) and ATP (state 1), depending on ambient light conditions and the metabolic needs of the plant. Both NADPH and ATP are required to convert CO₂ to sucrose or starch, the fourth stage in photosynthesis, which we cover in the last section of this chapter.

(a)

State 1, linear electron flow

FIGURE 12-44 Phosphorylation of LHCII and the regulation of linear versus cyclic electron flow. (a, top) In normal sunlight, PSI and PSII are equally activated, and the photosystems are organized in state 1. In this arrangement, light-harvesting complex II (LHCII) is not phosphorylated and six copies of LHCII trimers together with several other light-harvesting proteins encircle a dimeric PSII reaction center in a tightly associated supercomplex in the grana (for clarity, molecular details of the supercomplexes not shown). As a result, PSII and PSI can function in parallel in linear electron flow. (a, bottom) When light excitation of the two photosystems is unbalanced (e.g., too much via PSII), LHCII becomes phosphorylated, dissociates from

PSII, and diffuses into the unstacked membranes, where it associates with PSI and its permanently associated LHCI. In this alternative supramolecular organization (state 2), most of the absorbed light energy is transferred to PSI, supporting cyclic electron flow and ATP production but no formation of NADPH and thus no CO_2 fixation. (b) Model of a PSI “super-supercomplex” involved with *Ndh-independent cyclic electron flow* that was isolated from green algae in stage 2. The super-supercomplex contains multiple complexes, including the integral membrane protein PGRL1 that was identified by genetic analysis. (Adapted from F. A. Wollman, 2001, *EMBO J.* **20**:3623; and M. Iwai, et al., 2010, *Nature* **464**:1210–1213.)

KEY CONCEPTS of Section 12.6

Molecular Analysis of Photosystems

- In the single photosystem of purple bacteria, cyclic electron flow from light-excited, special-pair chlorophyll *a* molecules in the reaction center generates a proton-motive force, which is used mainly to power ATP synthesis by the F_0F_1 complex in the plasma membrane (see Figure 12-38).
- Plants contain two photosystems, PSI and PSII, which have different functions and are physically separated in the thylakoid membrane. PSII converts H_2O into O_2 , and PSI reduces NADP^+ to NADPH. Cyanobacteria have two analogous photosystems.
- In chloroplasts, light energy absorbed by light-harvesting complexes (LHCs) is transferred to chlorophyll *a* molecules in the reaction centers (P_{680} in PSII and P_{700} in PSI).
- Electrons flow through PSII via the same carriers that are present in the bacterial photosystem. In contrast to the bacterial

system, photochemically oxidized P_{680}^+ in PSII is regenerated to P_{680} by electrons derived from the evolution of O_2 from H_2O (see Figure 12-39, left).

- In linear electron flow, photochemically oxidized P_{700}^+ in PSI is reduced, regenerating P_{700} , by electrons transferred from PSII via the cytochrome *b_f* complex and soluble plastocyanin. Electrons released from P_{700} following excitation of PSI are transported via several carriers ultimately to NADP^+ , generating NADPH (see Figure 12-39, right).
- The absorption of light by pigments in the chloroplast can generate reactive oxygen species (ROS), including singlet oxygen, $^1\text{O}_2$, and hydrogen peroxide, H_2O_2 . In small amounts they are not toxic and are used as intracellular signaling molecules to control cellular metabolism. In larger amounts they can be toxic. Small molecule scavengers and antioxidant enzymes help to protect against ROS-induced damage; however, singlet oxygen damage to the D1 subunit of PSII still occurs, causing photoinhibition. An HSP70 chaperone helps PSII recover from the damage.

- In contrast to linear electron flow, which requires both PSII and PSI, cyclic electron flow in plants involves only PSI. In this pathway, neither net NADPH nor O_2 is formed although a proton-motive force is generated. Very large super-complexes can be involved in cyclic electron flow.
- Reversible phosphorylation and dephosphorylation of the light-harvesting complex II (LHCII) control the functional organization of the photosynthetic apparatus in thylakoid membranes. State 1 favors linear electron flow, whereas state 2 favors cyclic electron flow (see Figure 12-44).

12.7 CO_2 Metabolism During Photosynthesis

Chloroplasts perform many metabolic reactions in green leaves. In addition to CO_2 fixation—incorporation of gaseous CO_2 into small organic molecules and then sugars—the synthesis of almost all amino acids, all fatty acids and carotenes, all pyrimidines, and probably all purines occurs in chloroplasts. However, the synthesis of sugars from CO_2 is the most extensively studied biosynthetic pathway in plant cells. We first consider the unique pathway, known as the **Calvin cycle** (after discoverer Melvin Calvin), that fixes CO_2 into three-carbon compounds, powered by energy released during ATP hydrolysis and oxidation of NADPH.

Rubisco Fixes CO_2 in the Chloroplast Stroma

The enzyme **ribulose 1,5-bisphosphate carboxylase**, or **rubisco**, fixes CO_2 into precursor molecules that are subsequently converted into carbohydrates. Rubisco is located in the stromal space of the chloroplast. This enzyme adds CO_2 to the five-carbon sugar ribulose 1,5-bisphosphate to form two molecules of the three-carbon-containing 3-phosphoglycerate (Figure 12-45). Rubisco is a large enzyme (~500 kDa), with the most common form composed of eight identical large and eight

identical small subunits. One subunit is encoded in chloroplast DNA; the other, in nuclear DNA. Because the catalytic rate of rubisco is quite low, many copies of the enzyme are needed to fix sufficient CO_2 . Indeed, this enzyme makes up almost 50 percent of the chloroplast soluble protein and is believed to be the most abundant protein on earth. It is estimated that rubisco fixes more than 10^{11} tons of atmospheric CO_2 each year.

When photosynthetic algae are exposed to a brief pulse of ^{14}C -labeled CO_2 and the cells are then quickly disrupted, 3-phosphoglycerate is radiolabeled most rapidly, and all the radioactivity is found in the carboxyl group. Because CO_2 is initially incorporated into a three-carbon compound, the Calvin cycle is also called the **C_3 pathway** of carbon fixation (Figure 12-46).

The fate of 3-phosphoglycerate formed by rubisco is complex: some is converted to hexoses incorporated into starch or sucrose, but some is used to regenerate ribulose 1,5-bisphosphate. At least nine enzymes are required to regenerate ribulose 1,5-bisphosphate from 3-phosphoglycerate. Quantitatively, for every 12 molecules of 3-phosphoglycerate generated by rubisco (a total of 36 C atoms), 2 of them (6 C atoms) are converted to 2 molecules of glyceraldehyde 3-phosphate (and later to 1 hexose), whereas 10 molecules (30 C atoms) are converted to 6 molecules of ribulose 1,5-bisphosphate (Figure 12-46, *top*). The fixation of 6 CO_2 molecules and the net formation of 2 glyceraldehyde 3-phosphate molecules require the consumption of 18 ATPs and 12 NADPHs, generated by the light-requiring processes of photosynthesis.

Synthesis of Sucrose Using Fixed CO_2 Is Completed in the Cytosol

After its formation in the chloroplast stroma, glyceraldehyde 3-phosphate is transported to the cytosol in exchange for phosphate. The final steps of sucrose synthesis (Figure 12-46, *bottom*) occur in the cytosol of leaf cells.

An antiporter transport protein in the chloroplast membrane brings fixed CO_2 (as glyceraldehyde 3-phosphate) into the cytosol when the cell is exporting sucrose vigorously. No

FIGURE 12-45 The initial reaction of rubisco that fixes CO_2 into organic compounds. In this reaction, catalyzed by ribulose 1,5-bisphosphate carboxylase (rubisco), CO_2 condenses with the

five-carbon sugar ribulose 1,5-bisphosphate. The products are two molecules of 3-phosphoglycerate.

FIGURE 12-46 The pathway of carbon during photosynthesis.

(Top) Six molecules of CO_2 are converted into two molecules of glyceraldehyde 3-phosphate. These reactions, which constitute the Calvin cycle, occur in the stroma of the chloroplast. Via the phosphate/triosephosphate antiporter, some glyceraldehyde 3-phosphate is transported to the cytosol in exchange for phosphate. (Bottom) In the cytosol, an exergonic series of reactions converts glyceraldehyde 3-phosphate to fructose 1,6-bisphosphate. Two molecules of fructose 1,6-bisphosphate are used to synthesize one of the disaccharide sucrose. Some glyceraldehyde 3-phosphate (not shown here) is also converted to amino acids and fats, compounds essential for plant growth.

fixed CO_2 leaves the chloroplast unless phosphate is fed into it to replace the phosphate carried out of the stroma in the form of glyceraldehyde 3-phosphate. During the synthesis of sucrose from glyceraldehyde 3-phosphate, inorganic phosphate groups are released (Figure 12-46, bottom left). Thus the synthesis of sucrose facilitates the transport of additional glyceraldehyde 3-phosphate from the chloroplast to the cytosol by providing phosphate for the antiporter. It is worth noting that glyceraldehyde 3-phosphate is a glycolytic intermediate and that the mechanism of the conversion of glyceraldehyde 3-phosphate to hexoses is almost the reverse of that in glycolysis.

The synthesis of starch is more complex. The key monomer substrate used to build large starch polymers is ADP-glucose. This polymerization takes place in the stroma and starch polymers are stored in densely packed crystalline aggregates called granules. The enzymes that generate ADP-glucose from glucose-1 phosphate and ATP are found in both the stroma and the cytosol, indicating that hexoses of various structures in the cytosol are imported into the stroma for starch synthesis.

Light and Rubisco Activase Stimulate CO_2 Fixation

The Calvin cycle enzymes that catalyze CO_2 fixation are rapidly inactivated in the dark, thereby conserving ATP that is generated in the dark (for example by the breakdown of starch) for other synthetic reactions, such as lipid and amino acid biosynthesis. One mechanism that contributes to this control is the pH dependence of several Calvin cycle enzymes. Because protons are transported from the stroma into the thylakoid lumen during photoelectron transport (see Figure 12-39), the pH of the stroma increases from ~ 7 in the dark to ~ 8 in the light. The increased activity of several Calvin cycle enzymes at the higher pH promotes CO_2 fixation in the light.

A stromal protein called *thioredoxin* (Tx) also plays a role in controlling some Calvin cycle enzymes. In the dark, thioredoxin contains a disulfide bond; in the light, electrons are transferred from PSI, via ferredoxin, to thioredoxin, reducing its disulfide bond:

Reduced thioredoxin then activates several Calvin cycle enzymes by reducing their disulfide bonds. In the dark, when thioredoxin becomes reoxidized, these enzymes are reoxidized and so inactivated. Thus these enzymes are sensitive to the redox state of the stroma, which in turn is light sensitive—an elegant mechanism for regulating enzymatic activity by light.

Rubisco is one such light/redox-sensitive enzyme, although its regulation is very complex and not yet fully understood. Rubisco is spontaneously activated in the presence of high CO_2 and Mg^{2+} concentrations. The activating reaction entails covalent addition of CO_2 to the side-chain amino group of a lysine in the active site, forming a carbamate group that then binds a Mg^{2+} ion required for enzymatic activity. Under normal conditions, however, with ambient levels of CO_2 , the reaction is slow and usually requires catalysis by *rubisco activase*, a member of the AAA+ family of ATPases. Rubisco activase hydrolyzes ATP and uses the energy released to clear the active site of rubisco so that CO_2 can be added to its active site lysine. Rubisco activase also accelerates an activating conformational change in rubisco (inactive-closed to active-opened state). The regulation of rubisco activase by thioredoxin is, at least in part in some species, responsible for rubisco's light/redox sensitivity. Furthermore, rubisco activase's activity is sensitive to the ratio of ATP:ADP. If that ratio is low (relatively high ADP), then the activase will not activate rubisco (and so the cell will expend less of its scarce ATP to fix carbon). Photosynthesis is sensitive to a variety of typical plant stresses—moderate heat, cool temperatures, drought (limited water), high salt, high light intensity, and UV radiation. At least some of these influence CO_2 fixation by reducing the activity of rubisco activase and thus rubisco. Inhibition of CO_2 fixation reduces consumption of NADPH. Under strong light conditions the excess NADPH/NADP⁺ ratio can reduce electron flow to NADP⁺ and increase leakage to O_2 , resulting in increased ROS formation, which can interfere with a variety of cellular processes. Given the key role of rubisco in controlling energy utilization and carbon flux—both in an individual chloroplast and, in a sense, throughout the entire biosphere—it is not surprising that its activity is tightly regulated.

Photorespiration Competes with Carbon Fixation and Is Reduced in C_4 Plants

As noted above, rubisco catalyzes the incorporation of CO_2 into ribulose 1,5-bisphosphate as part of photosynthesis. It can catalyze a second, distinct, and *competing* reaction with the same substrate—ribulose 1,5-bisphosphate—but with O_2 in place of CO_2 as a second substrate, in a process known as **photorespiration** (Figure 12-47). The products of the second reaction are one molecule of 3-phosphoglycerate and one molecule of the two-carbon compound phosphoglycolate. The carbon-fixing reaction is favored when the ambient CO_2 concentration is relatively high, whereas photorespiration is favored when CO_2 is low and O_2 relatively high. Photorespiration takes place in light, consumes O_2 , and converts ribulose

FIGURE 12-47 CO₂ fixation and photorespiration. These competing pathways are both initiated by ribulose 1,5-bisphosphate carboxylase (rubisco), and both utilize ribulose 1,5-bisphosphate. CO₂ fixation, pathway 1, is favored by high CO₂ and low O₂ pressures; photorespiration, pathway 2, occurs at low CO₂ and high O₂ pressures (that is, under normal atmospheric conditions). Phosphoglycolate is recycled via a

complex set of reactions that take place in peroxisomes and mitochondria, as well as chloroplasts. The net result: for every two molecules of phosphoglycolate formed by photorespiration (four C atoms), one molecule of 3-phosphoglycerate is ultimately formed and recycled and one molecule of CO₂ is lost.

1,5-bisphosphate in part to CO₂. As Figure 12-47 shows, photorespiration is wasteful to the energy economy of the plant: it consumes ATP and O₂, and it generates CO₂ without fixing carbon. Indeed, when CO₂ is low and O₂ is high, much of the CO₂ fixed by the Calvin cycle is lost as the result of photorespiration. Recent studies have suggested that this surprising, wasteful alternative reaction catalyzed by rubisco may be a consequence of the inherent difficulty the enzyme has in specifically binding the relatively featureless CO₂ molecule and of the ability of both CO₂ and O₂ to react and form distinct products with the same initial enzyme/ribulose 1,5-bisphosphate intermediate.

Excessive photorespiration could become a problem for plants in a hot, dry environment, because they must keep the gas-exchange pores (stomata) in their leaves closed much of the time to prevent excessive loss of moisture. As a consequence, the CO₂ level inside the leaf can fall below the K_m of rubisco for CO₂. Under these conditions, the rate of photosynthesis is slowed, photorespiration is greatly favored, and the plant might be in danger of fixing inadequate amounts of CO₂. Corn, sugarcane, crabgrass, and other plants that can grow in hot, dry environments have evolved a way to avoid this problem by utilizing a two-step pathway of CO₂ fixation in which a CO₂-hoarding step precedes the Calvin cycle. The pathway has been named the *C₄ pathway* because [¹⁴C]CO₂ labeling showed that the first radioactive molecules formed during photosynthesis in this pathway are four-carbon compounds, such as oxaloacetate and malate, rather than the three-carbon molecules that initiate the Calvin cycle (*C₃ pathway*).

The *C₄ pathway* involves two types of cells: *mesophyll cells*, which are adjacent to the air spaces in the leaf interior, and *bundle sheath cells*, which surround the vascular tissue and are sequestered away from the high oxygen levels to which mesophyll cells are exposed (Figure 12-48a). In the mesophyll cells of *C₄ plants*, phosphoenolpyruvate, a three-carbon molecule derived from pyruvate, reacts with CO₂ to generate oxaloacetate, a four-carbon compound (Figure 12-48b). The enzyme that catalyzes this reaction, *phosphoenolpyruvate carboxylase*, is found almost exclusively in *C₄ plants* and unlike rubisco is insensitive to O₂. The overall reaction from pyruvate to oxaloacetate involves the hydrolysis of one ATP and has a negative ΔG . Therefore, CO₂ fixation will proceed even when the CO₂ concentration is low. The oxaloacetate formed in mesophyll cells is reduced to malate, which is transferred by a special transporter to the bundle sheath cells, where the CO₂ released by decarboxylation enters the Calvin cycle (Figure 12-48b).

Because of the transport of CO₂ from mesophyll cells, the CO₂ concentration in the bundle sheath cells of *C₄ plants* is much higher than it is in the normal atmosphere. Bundle sheath cells are also unusual in that they lack PSII and carry out only cyclic electron flow catalyzed by PSI, so no O₂ is evolved. The high CO₂ and reduced O₂ concentrations in the bundle sheath cells favor the fixation of CO₂ by rubisco to form 3-phosphoglycerate and inhibit the utilization of ribulose 1,5-bisphosphate in photorespiration.

In contrast, the high O₂ concentration in the atmosphere favors photorespiration in the mesophyll cells of *C₃ plants* (pathway 2 in Figure 12-47); as a result, as much as 50 percent

FIGURE 12-48 Leaf anatomy of C_4 plants and the C_4 pathway.

(a) In C_4 plants, bundle sheath cells line the vascular bundles containing the xylem and phloem. Mesophyll cells, which are adjacent to the substomal air spaces, can assimilate CO_2 into four-carbon molecules at low ambient CO_2 and deliver it to the interior bundle sheath cells. Bundle sheath cells contain abundant chloroplasts and are the sites of photosynthesis and sucrose

synthesis. Sucrose is carried to the rest of the plant via the phloem. In C_3 plants, which lack bundle sheath cells, the Calvin cycle operates in the mesophyll cells to fix CO_2 . (b) The key enzyme in the C_4 pathway is phosphoenolpyruvate carboxylase, which assimilates CO_2 to form oxaloacetate in mesophyll cells. Decarboxylation of malate or other C_4 intermediates in bundle sheath cells releases CO_2 , which enters the standard Calvin cycle (see Figure 12-46, top).

of the carbon fixed by rubisco may be reoxidized to CO_2 in C_3 plants. C_4 plants are superior to C_3 plants in utilizing the available CO_2 , because the C_4 enzyme phosphoenolpyruvate carboxylase has a higher affinity for CO_2 than does rubisco in the Calvin cycle. However, one ATP is converted to one AMP in the cyclic C_4 process (to generate phosphoenolpyruvate from pyruvate); thus the overall efficiency of the photosynthetic production of sugars from NADPH and ATP is

lower than it is in C_3 plants, which use only the Calvin cycle for CO_2 fixation. Nonetheless, the net rates of photosynthesis for C_4 grasses, such as corn or sugarcane, can be two to three times the rates for otherwise similar C_3 grasses, such as wheat, rice, or oats, owing to the elimination of losses from photorespiration.

Of the two carbohydrate products of photosynthesis, starch remains in the mesophyll cells of C_3 plants and the bundle

sheaf cells in C_4 plants. In these cells, starch is subjected to glycolysis, mainly in the dark, forming ATP, NADH, and small molecules that are used as building blocks for the synthesis of amino acids, lipids, and other cellular constituents. Sucrose, in contrast, is exported from the photosynthetic cells and transported throughout the plant.

KEY CONCEPTS of Section 12.7

CO_2 Metabolism During Photosynthesis

- In the Calvin cycle, CO_2 is fixed into organic molecules in a series of reactions that occur in the chloroplast stroma. The initial reaction, catalyzed by rubisco, forms a three-carbon intermediate. Some of the glyceraldehyde 3-phosphate generated in the cycle is transported to the cytosol and converted to sucrose (see Figure 12-46).
- The light-dependent activation of several Calvin cycle enzymes and other mechanisms increases fixation of CO_2 in the light. The redox state of the stroma plays a key role in this regulation as does the regulation of the activity of rubisco by rubisco activase.
- In C_3 plants, a substantial fraction of the CO_2 fixed by the Calvin cycle can be lost as the result of photorespiration, a wasteful reaction catalyzed by rubisco that is favored at low CO_2 and high O_2 levels (see Figure 12-47).
- In C_4 plants, CO_2 is fixed initially in the outer mesophyll cells by reaction with phosphoenolpyruvate. The four-carbon molecules so generated are shuttled to the interior bundle sheath cells, where the CO_2 is released and then used in the Calvin cycle. The rate of photorespiration in C_4 plants is much lower than it is in C_3 plants.

Perspectives for the Future

Although the overall processes of photosynthesis and mitochondrial oxidation are well understood, many important details remain to be uncovered. For example, while increasingly high-resolution structures of complexes and supercomplexes are being determined, many of the mechanistic details underlying the function and regulation of electron transport chains and their associated reactions (proton translocation, oxygen generation, etc.) remain to be established. Moving beyond this static picture of these remarkably complex structures requires additional biophysical analysis of the dynamics underlying their activities. For example, we do not know with certainty the pathway taken by protons during proton pumping in some of the electron transport complexes.

Although the binding-change mechanism for ATP synthesis by the F_0F_1 complex is now generally accepted, we do not understand precisely how conformational changes in each β subunit are coupled to the cyclical binding of ADP

and P_i , formation of ATP, and then release of ATP. Nor has the detailed pathway of proton movement through the c ring been defined. In addition, many questions remain about the precise mechanism of action of transport proteins in the inner mitochondrial and chloroplast membranes that play key roles in oxidative phosphorylation and photosynthesis.

We now know that release of cytochrome c and other proteins from the intermembrane space of mitochondria into the cytosol plays a major role in triggering apoptosis (Chapter 21). Certain members of the Bcl-2 family of apoptotic proteins and ion channels localized in part to the outer mitochondrial membrane participate in this process. The connections between energy metabolism and mechanisms underlying apoptosis remain to be clearly defined.

The recognition over the past decade of the importance of mitochondrial dynamics (e.g., fusion and fission) to mitochondrial function has set the stage for detailed genetic molecular analysis of these processes. Several of the key players in fusion and fission have been identified, but many additional components have yet to be discovered, and the mechanisms of these complex processes, such as the coordinated fusion of inner membranes with each other and outer membranes with each other, are waiting to be elucidated.

The role of reactive oxygen species (ROS) in cell biology is an active area of research. ROS-mediated cellular stress is now thought to play a role in many diseases and will likely continue to be a major area of research in the coming years. In addition to their role in cellular oxidative stress, ROS can also serve as signaling molecules that alter nuclear gene expression, sometimes called retrograde signaling. It appears that ROS and other small molecules released from the mitochondrion and chloroplast can be used to inform the nucleus about the metabolic status of each organelle and thus permit appropriate regulation of gene expression in response. In some cases this involves compensatory activation of protective genes. In others it may involve increasing or decreasing the production of nuclear-encoded proteins to insure proper organelle functioning. The mechanisms of these signaling pathways, which in some cases involve redox reactions with thiols on signaling molecules, remain to be determined.

As we better understand the mechanisms underlying photosynthesis, particularly the action of rubisco—both its regulation and its influence on photosynthesis and overall chloroplast metabolism—it is possible that we will be able to exploit these insights to improve crop yields to provide abundant and inexpensive food to all who need it.

Key Terms

aerobic oxidation 517

ATP synthase 544

binding-change mechanism
547

Calvin cycle 567

carbon fixation 553

catabolism 520

C_4 pathway 570

chemiosmosis 518
 chlorophylls 552
 chloroplast 552
 citric acid cycle 520
 coenzyme Q 535
 cytochrome 535
 electron carrier 529
 electron transport chain 519
 endosymbiont hypothesis 545
 fermentation 522
 flavin adenine dinucleotide (FAD) 520
 F_0F_1 complex 544
 glycolysis 520
 mitochondrion 524
 mitochondrial inner membrane 525
 nicotinamide adenine dinucleotide (NAD^+) 520
 oxidative phosphorylation 519
 peroxisomal oxidation 531
 photoelectron transport 556
 photorespiration 569
 photosynthesis 517
 photosystem 555
 prosthetic group 534
 proton-motive force 519
 Q cycle 538
 reactive oxygen species 541
 reduction potential 539
 respiration 519
 respiratory control 551
 rubisco 567
 substrate-level phosphorylation 520
 thylakoids 553
 uncoupler 551

Review the Concepts

1. The proton-motive force (pmf) is essential for both mitochondrial and chloroplast function. What produces the pmf, and what is its relationship to ATP? The compound 2,4-dinitrophenol (DNP), which was used in diet pills in the 1930s but later shown to have dangerous side effects, allows protons to diffuse across membranes. Why is it dangerous to consume DNP?
2. The mitochondrial inner membrane exhibits all of the fundamental characteristics of a typical cell membrane, but it also has several unique characteristics that are closely associated with its role in oxidative phosphorylation. What are these unique characteristics? How does each contribute to the function of the inner membrane?
3. Maximal production of ATP from glucose involves the reactions of glycolysis, the citric acid cycle, and the electron transport chain. Which of these reactions requires O_2 , and why? Which, in certain organisms or physiological conditions, can proceed in the absence of O_2 ?
4. Fermentation permits the continued extraction of energy from glucose in the absence of oxygen. If glucose catabolism is anaerobic, why is fermentation necessary for glycolysis to continue?
5. Describe the step-by-step process by which electrons from glucose catabolism in the cytoplasm are transferred to the electron transport chain in the mitochondrial inner membrane. In your answer, note whether the electron transfer at each step is direct or indirect.
6. Mitochondrial oxidation of fatty acids is a major source of ATP, yet fatty acids can be oxidized elsewhere. What organelle, besides the mitochondrion, can oxidize fatty acids? What is the fundamental difference between oxidation occurring in this organelle and mitochondrial oxidation?
7. Each of the cytochromes in the mitochondrion contains prosthetic groups. What is a prosthetic group? Which type of prosthetic group is associated with the cytochromes? What property of the various cytochromes ensures unidirectional electron flow along the electron transport chain?
8. The electron transport chain consists of a number of multiprotein complexes, which work in conjunction to pass electrons from an electron carrier, like NADH, to O_2 . What is the role of these complexes in ATP synthesis? It has been demonstrated that respiration supercomplexes contain all the protein components necessary for respiration. Why is this beneficial for ATP synthesis, and what is one way that the existence of supercomplexes has been demonstrated experimentally? Coenzyme Q (CoQ) is not a protein, but a small, hydrophobic molecule. Why is it important for the functioning of the electron transport chain that CoQ is a hydrophobic molecule?
9. It is estimated that each electron pair donated by NADH leads to the synthesis of approximately three ATP molecules, whereas each electron pair donated by $FADH_2$ leads to the synthesis of approximately two ATP molecules. What is the underlying reason for the difference in yield for electrons donated by $FADH_2$ versus NADH?
10. Describe the main functions of the different components of ATP synthase enzyme in the mitochondrion. A structurally similar enzyme is responsible for the acidification of lysosomes and endosomes. Given what you know about the mechanism of ATP synthesis, explain how this acidification might occur.
11. Much of our understanding of ATP synthase is derived from research on aerobic bacteria. What makes these organisms useful for this research? Where do the reactions of glycolysis, the citric acid cycle, and the electron transport chain occur in these organisms? Where is the pmf generated in aerobic bacteria? What other cellular processes depend on the pmf in these organisms?
12. An important function of the mitochondrial inner membrane is to provide a selectively permeable barrier to the movement of water-soluble molecules and thus generate different chemical environments on either side of the membrane. However, many of the substrates and products of oxidative phosphorylation are water soluble and must cross the inner membrane. How does this transport occur?
13. The Q cycle plays a major role in the electron transport chain of mitochondria, chloroplasts, and bacteria. What is the function of the Q cycle, and how does it carry out this function? What electron transport components participate in the Q cycle in mitochondria, in purple bacteria, and in chloroplasts?
14. True or False: Since ATP is generated in chloroplasts, cells capable of undergoing photosynthesis do not require mitochondria. Explain. Name and describe the idea that explains how mitochondria and chloroplasts are thought to have originated in eukaryotic cells.

15. Write the overall reaction of oxygen-generating photosynthesis. Explain the following statement: the O_2 generated by photosynthesis is simply a by-product of the pathway's generation of carbohydrates and ATP.

16. Photosynthesis can be divided into multiple stages. What are the stages of photosynthesis, and where does each occur within the chloroplast? Where is the sucrose produced by photosynthesis generated?

17. The photosystems responsible for absorption of light energy are each composed of two linked components, the reaction center and an antenna complex. What is the pigment composition and role of each component in the process of light absorption? What evidence exists that the pigments found in these components are involved in photosynthesis?

18. Photosynthesis in green and purple bacteria does not produce O_2 . Why? How can these organisms still use photosynthesis to produce ATP? What molecules serve as electron donors in these organisms?

19. Chloroplasts contain two photosystems. What is the function of each? For linear electron flow, diagram the flow of electrons from photon absorption to NADPH formation. What does the energy stored in the form of NADPH synthesize?

20. The Calvin cycle reactions that fix CO_2 do not function in the dark. What are the likely reasons for this? How are these reactions regulated by light?

21. Rubisco, which may be the most abundant protein on earth, plays a key role in the synthesis of carbohydrates in organisms that use photosynthesis. What is rubisco, where is it located, and what function does it serve?

c. After the vesicles were incubated in buffer containing ADP, P_i , and O_2 for a period of time, addition of dinitrophenol caused an increase in BCECF fluorescence. In contrast, addition of valinomycin produced only a small transient effect. Explain these findings.

d. What result would you expect to see if the source of the mitochondrial membrane were brown-fat mitochondria? Explain.

e. Chloroplasts could also be used as a source of membranes in a similar experiment (as in part a) involving BCECF. In this case, the BCECF would be surrounded by what membrane? How would the fluorescence change upon addition of light, ADP, and P_i ?

Analyze the Data

A proton gradient can be analyzed with fluorescent dyes whose emission-intensity profiles depend on pH. One of the most useful dyes for measuring the pH gradient across mitochondrial membranes is the membrane-impermeant, water-soluble fluorophore 2',7'-bis-(2-carboxyethyl)-5(6)-carboxyfluorescein (BCECF). The effect of pH on the emission intensity of BCECF, excited at 505 nm, is shown in the accompanying figure. In one study, sealed vesicles containing this compound were prepared by mixing unsealed, isolated inner mitochondrial membranes with BCECF; after resealing of the membranes, the vesicles were collected by centrifugation and then resuspended in nonfluorescent medium.

a. When these vesicles were incubated in a physiological buffer containing NADH, ADP, P_i , and O_2 , the fluorescence of BCECF trapped inside gradually decreased in intensity. What does this decrease in fluorescent intensity suggest about this vesicular preparation?

b. How would you expect the concentrations of ADP, P_i , and O_2 to change during the course of the experiment described in part a? Why?

Moving Proteins into Membranes and Organelles

A typical mammalian cell contains up to 10,000 different kinds of proteins; a yeast cell, about 5000. The vast majority of these proteins are synthesized by cytosolic ribosomes, and many remain within the cytosol (Chapter 4). However, as many as half of the different kinds of proteins produced in a typical cell are delivered to one or another of the various membrane-bounded organelles within the cell or to the cell surface. For example, many receptor proteins and transporter proteins must be delivered to the plasma membrane, some water-soluble enzymes such as RNA and DNA polymerases must be targeted to the nucleus, and components of the extracellular matrix as well as digestive enzymes and polypeptide signaling molecules must be directed to the cell surface for secretion from the cell. These and all the other proteins produced by a cell must reach their correct locations for the cell to function properly.

The delivery of newly synthesized proteins to their proper cellular destinations, usually referred to as *protein targeting*

or *protein sorting*, encompasses two very different kinds of processes: signal-based targeting and vesicle-based trafficking. The first general process involves targeting of a newly synthesized protein from the cytoplasm to an intracellular organelle. Targeting can occur during translation or soon after synthesis of the protein is complete. For membrane proteins, targeting leads to insertion of the protein into the lipid bilayer of the membrane, whereas for water-soluble proteins, targeting leads to translocation of the entire protein across the membrane into the aqueous interior of the organelle. Proteins are sorted to the endoplasmic reticulum (ER), mitochondria, chloroplasts, peroxisomes, and nucleus by this general process (Figure 13-1).

The second general sorting process is known as the **secretory pathway**, and involves transport of proteins from the ER to their final destination within membrane-enclosed vesicles. For many proteins, including those that make up the extracellular matrix, the final destination is the outside of the cell (hence the name); integral membrane proteins are also

FIGURE 13-1 Overview of major protein-sorting pathways in eukaryotes. All nuclear-encoded mRNAs are translated on cytosolic ribosomes. *Right (nonsecretory pathways):* Synthesis of proteins lacking an ER signal sequence is completed on free ribosomes (step 1). Those proteins that contain no targeting sequence are released into the cytosol and remain there (step 2). Proteins with an organelle-specific targeting sequence (pink) first are released into the cytosol (step 2) but then are imported into mitochondria, chloroplasts, peroxisomes, or the nucleus (steps 3–6). Mitochondrial and chloroplast proteins typically pass through the outer and inner membranes to enter the matrix or stromal space, respectively. Other proteins are sorted to other

subcompartments of these organelles by additional sorting steps. Nuclear proteins enter and exit through visible pores in the nuclear envelope. *Left (secretory pathway):* Ribosomes synthesizing nascent proteins in the secretory pathway are directed to the rough endoplasmic reticulum (ER) by an ER signal sequence (pink; steps 1, 2). After translation is completed on the ER, these proteins can move via transport vesicles to the Golgi complex (step 3). Further sorting delivers proteins either to the plasma membrane or to lysosomes (steps 4a, 4b). The vesicle-based processes underlying the secretory pathway (steps 2, 4, shaded box) are discussed in Chapter 14.

transported to the Golgi, lysosome, and plasma membrane by this process. The secretory pathway begins in the ER; thus all proteins slated to enter the secretory pathway are initially targeted to this organelle.

Targeting to the ER generally involves *nascent* proteins still in the process of being synthesized on a ribosome. Newly made proteins are thus extruded from the ribosome directly into the

ER membrane. Once translocated across the ER membrane, proteins are assembled into their native conformation by protein-folding catalysts present in the lumen of the ER. Indeed, the ER is the location where about one-third of the proteins in a typical cell fold into their native conformations, and most of the resident ER proteins either directly or indirectly contribute to the folding process. As part of the folding

process, proteins also undergo specific post-translational modifications in the ER. These processes are monitored carefully, and only after their folding and assembly is complete are proteins permitted to be transported out of the ER to other destinations. Proteins whose final destination is the Golgi, lysosome, plasma membrane, or cell exterior are transported along the secretory pathway by the action of small vesicles that bud from the membrane of one organelle and then fuse with the membrane of another (see Figure 13-1, *shaded box*). We discuss vesicle-based protein trafficking in the next chapter because mechanistically it differs significantly from non-vesicle-based protein targeting to intracellular organelles.

In this chapter, we examine how proteins are targeted to five intracellular organelles: ER, mitochondria, chloroplast, peroxisome, and nucleus. Two features of this protein-targeting process initially were quite baffling: how a given protein could be directed to only one specific membrane, and how relatively large hydrophilic protein molecules could be translocated across a hydrophobic membrane without disrupting the bilayer as a barrier to ions and small molecules. Using a combination of biochemical purification methods and genetic screens for identifying mutants unable to execute particular translocation steps, cell biologists have identified many of the cellular components required for translocation across each of the different intracellular membranes. In addition, many of the major translocation processes in the cell have been reconstituted using the purified protein components incorporated into artificial lipid bilayers. Such *in vitro* systems can be freely manipulated experimentally.

These studies have shown that, despite some variations, the same basic mechanisms govern protein sorting to all the various intracellular organelles. We now know, for instance, that the information to target a protein to a particular organelle destination is encoded within the amino acid sequence of the protein itself, usually within sequences of about 20 amino acids, known generically as **signal sequences** (see Figure 13-1); these are also called *uptake-targeting sequences* or *signal peptides*. Such targeting sequences usually occur at the N-terminus of a protein and are thus the first part of a protein to be synthesized. More rarely, targeting sequences can occur at either the C-terminus or within the interior of a protein sequence. Each organelle carries a set of receptor proteins that bind only to specific kinds of signal sequences, thus ensuring that the information encoded in a signal sequence governs the specificity of targeting. Once a protein containing a signal sequence has interacted with the corresponding receptor, the protein chain is transferred to some kind of *translocation channel* that allows the protein to pass into or through the membrane bilayer. The unidirectional transfer of a protein into an organelle, without sliding back out into the cytoplasm, is usually achieved by coupling translocation to an energetically favorable process such as hydrolysis of GTP or ATP. Some proteins are subsequently sorted further to reach a subcompartment within the target organelle; such sorting depends on yet other signal sequences and other receptor proteins. Finally, signal sequences often are removed from the mature protein by specific proteases once translocation across the membrane is completed.

For each of the protein-targeting events discussed in this chapter, we will seek to answer four fundamental questions:

1. What is the nature of the *signal sequence*, and what distinguishes it from other types of signal sequences?
2. What is the *receptor* for the signal sequence?
3. What is the structure of the *translocation channel* that allows transfer of proteins across the membrane bilayer? In particular, is the channel so narrow that proteins can pass through only in an unfolded state, or will it accommodate folded protein domains?
4. What is the source of *energy* that drives unidirectional transfer across the membrane?

In the first part of the chapter, we cover targeting of proteins to the ER, including the post-translational modifications that occur to proteins as they enter the secretory pathway. Targeting of proteins to the ER is the best-understood example of protein targeting, and will serve as an exemplar of the process in general. We then describe targeting of proteins to mitochondria, chloroplasts, and peroxisomes. Finally, we cover the transport of proteins into and out of the nucleus through nuclear pores.

13.1 Targeting Proteins to and Across the ER Membrane

All eukaryotic cells have an endoplasmic reticulum (ER). The ER is a large, convoluted organelle made up of tubules and flattened sacs, whose membrane is continuous with the membrane of the nucleus. The ER membrane is where cellular lipids are synthesized (Chapter 10), and the ER is where most membrane proteins are assembled, including those of the plasma membrane and the membrane of the lysosomes, ER, and Golgi. In addition, all soluble proteins that will eventually be secreted from the cell—as well as those destined for the lumen of the ER, Golgi, or lysosomes—are initially delivered to the ER lumen (see Figure 13-1). Since the ER plays such an important role in protein secretion, we refer to the pathway of protein trafficking that flows through the ER as the “secretory pathway.” For simplicity, we will refer to all proteins initially targeted to the ER as “secretory proteins,” *but* keep in mind that not all proteins that are targeted to the ER are actually secreted from the cell.

In this first section, we discuss how proteins are initially identified as secretory proteins, and how such proteins are translocated across the ER membrane. We deal first with soluble proteins—those that pass all the way through the ER membrane, into the lumen. In the next section, we discuss integral membrane proteins, which are inserted into the ER membrane.

Pulse-Labeling Experiments with Purified ER Membranes Demonstrated That Secreted Proteins Cross the ER Membrane

Although all cells secrete a variety of proteins (e.g., extracellular matrix proteins), certain types of cells are specialized for secretion of large amounts of specific proteins. Pancreatic

FIGURE 13-2 Structure of the rough ER. (a) Electron micrograph of ribosomes attached to the rough ER in a pancreatic acinar cell. Most of the proteins synthesized by this type of cell are to be secreted and are formed on membrane-attached ribosomes. A few membrane-unattached (free) ribosomes are evident; presumably, these are synthesizing cytosolic or other nonsecretory proteins. (b) Schematic representation of protein synthesis on the ER. Note that membrane-bound and free cytosolic ribosomes are identical. Membrane-bound ribosomes get recruited to the endoplasmic reticulum during protein synthesis of a polypeptide containing an ER signal sequence. [Part (a) courtesy of G. Palade.]

acinar cells, for instance, synthesize large quantities of several digestive enzymes that are secreted into ductules that lead to the intestine. Because such secretory cells contain the organelles of the secretory pathway (e.g., ER and Golgi) in great abundance, they have been widely used in studying this pathway, including the initial steps that occur at the ER membrane.

The sequence of events that occurs immediately after the synthesis of a secretory protein were first elucidated by pulse-labeling experiments with pancreatic acinar cells. In such cells, radioactively labeled amino acids are incorporated into secretory proteins as they are synthesized on ribosomes that are bound to the surface of the ER. The portion of the ER

that receives proteins entering the secretory pathway is known as the *rough ER* because it is so densely studded with ribosomes that its surface appears morphologically distinct from other ER membranes (Figure 13-2). From these experiments, it became clear that during or immediately after their synthesis on the ribosome, secretory proteins translocate across the ER membrane into the lumen of the ER.

To delineate the steps in the translocation process, it was necessary to isolate the ER from the rest of the cell. Isolation of intact ER with its delicate lacelike structure and interconnectedness with other organelles is not feasible. However, scientists discovered that after cells are homogenized, the rough ER breaks up into small closed vesicles with ribosomes on the outside, termed *rough microsomes*, which retain most of the biochemical properties of the ER, including the capability of protein translocation. The experiments depicted in Figure 13-3, in which microsomes isolated from pulse-labeled cells are treated with a protease, demonstrate that although secretory proteins are synthesized on ribosomes bound to the cytosolic face of the ER membrane, the polypeptides produced by these ribosomes end up within the lumen of ER vesicles. Experiments such as this raised the question of how polypeptides are recognized as secretory proteins shortly after their synthesis begins and how a nascent secretory protein is threaded across the ER membrane.

A Hydrophobic N-Terminal Signal Sequence Targets Nascent Secretory Proteins to the ER

After synthesis of a secretory protein begins on free ribosomes in the cytosol, a 16- to 30-residue ER signal sequence in the nascent protein directs the ribosome to the ER membrane and initiates translocation of the growing polypeptide across the ER membrane (see Figure 13-1, *left*). An ER signal sequence typically is located at the N-terminus of the protein, the first part of the protein to be synthesized. The signal sequences of different secretory proteins all contain one or more positively charged amino acids adjacent to a continuous stretch of 6–12 hydrophobic residues (known as the hydrophobic core), but otherwise they have little in common. For most secretory proteins, the signal sequence is cleaved from the protein while it is still elongating on the ribosome; thus signal sequences are usually not present in the “mature” proteins found in cells.

The hydrophobic core of ER signal sequences is essential for their function. For instance, the specific deletion of several of the hydrophobic amino acids from a signal sequence or the introduction of charged amino acids into the hydrophobic core by mutation can abolish the ability of the N-terminus of a protein to function as a signal sequence. As a consequence, the modified protein remains in the cytosol, unable to cross the ER membrane into the lumen. Conversely, signal sequences can be added to normally cytosolic proteins using recombinant DNA techniques. Provided the added sequence is sufficiently long and hydrophobic, such a modified cytosolic protein acquires the ability to be translocated to the ER lumen. Thus the hydrophobic residues in the core of ER signal sequences form a binding site that is critical

EXPERIMENTAL FIGURE 13-3 Secretory proteins enter the ER.

Labeling experiments demonstrate that secretory proteins are localized to the ER lumen shortly after synthesis. Cells are incubated for a brief time with radiolabeled amino acids so that only newly synthesized proteins become labeled. The cells then are homogenized, fracturing the plasma membrane and shearing the rough ER into small vesicles called *microsomes*. Because they have bound ribosomes, microsomes have a much greater buoyant density than other membranous organelles and can be separated from them by a combination of differential and sucrose density-gradient centrifugation (Chapter 9). The purified microsomes are treated with a protease in the presence or absence of a detergent. The labeled secretory proteins associated with the microsomes are digested by the protease only if the permeability barrier of the microsomal membrane is first destroyed by treatment with detergent. This finding indicates that the newly made proteins are inside the microsomes, equivalent to the lumen of the rough ER.

for the interaction of signal sequences with the machinery responsible for targeting the protein to the ER membrane.

Biochemical studies utilizing a cell-free protein-synthesizing system, mRNA encoding a secretory protein, and microsomes stripped of their own bound ribosomes have elucidated the

(a) Cell-free protein synthesis; no microsomes present

(b) Cell-free protein synthesis; microsomes present

EXPERIMENTAL FIGURE 13-4 Translation and translocation occur simultaneously.

Cell-free experiments demonstrate that translocation of secretory proteins into microsomes is coupled to translation. Treatment of microsomes with EDTA, which chelates Mg^{2+} ions, strips them of associated ribosomes, allowing isolation of ribosome-free microsomes, which are equivalent to ER membranes (see Figure 13-3). Protein synthesis is carried out in a cell-free system containing functional ribosomes, tRNAs, ATP, GTP, and cytosolic enzymes to which mRNA encoding a secretory protein is added. The secretory protein is synthesized in the absence of microsomes (a) but is translocated across the vesicle membrane and loses its signal sequence (resulting in a decrease in molecular weight) only if microsomes are present during protein synthesis (b).

function and fate of ER signal sequences. Initial experiments with this system demonstrated that a typical secretory protein is incorporated into microsomes and has its signal sequence removed only if the microsomes are present during protein synthesis. If microsomes are added to the system after protein synthesis is completed, no protein transport into the microsomes occurs (Figure 13-4). Subsequent experiments were designed to determine the precise stage of protein synthesis at which microsomes must be present in order for translocation to occur. In these experiments, microsomes were added to the reaction mixtures at different times after protein synthesis had begun. These experiments showed that microsomes must be added before the first 70 or so amino acids are translated in order for the completed secretory protein to be localized in the microsomal lumen. At this point, the first 40 amino acids or so protrude from

FIGURE 13-5 Structure of the signal-recognition particle (SRP).

(a) Signal-sequence binding domain: The bacterial Ffh protein is homologous to the portion of P54 that binds ER signal sequences. This surface model shows the binding domain in Ffh, which contains a large cleft lined with hydrophobic amino acids (purple) whose side chains interact with signal sequences. (b) GTP- and receptor-binding domain: The structure of GTP bound to FtsY (the bacterial homolog of the α subunit of SRP receptor) and Ffh proteins illustrates how the interaction between these proteins is controlled by GTP binding and hydrolysis. Ffh and FtsY each can bind to one molecule of GTP, and when Ffh and FtsY bind to each other, the two bound molecules of GTP fit in the interface between the protein subunits and stabilize the dimer. Assembly of the semisymmetrical dimer allows formation of two active sites for the hydrolysis of both bound GTP molecules. Hydrolysis to GDP destabilizes the interface, causing disassembly of the dimer.

[Part (a) adapted from R. J. Keenan et al., 1998, *Cell* **94**:181. Part (b) adapted from P. J. Focia et al., 2004, *Science* **303**:373.]

the ribosome, including the signal sequence that later will be cleaved off, and the next 30 or so amino acids are still buried within a channel in the ribosome (see Figure 4-26). Thus the transport of most secretory proteins into the ER lumen begins while the incompletely synthesized (nascent) protein is still bound to the ribosome, a process referred to as **cotranslational translocation**.

Cotranslational Translocation Is Initiated by Two GTP-Hydrolyzing Proteins

Since secretory proteins are synthesized in association with the ER membrane but not with any other cellular membrane, a signal-sequence recognition mechanism must target them there. The two key components in this targeting are the **signal-recognition particle (SRP)** and its receptor, located in the ER membrane. The SRP is a cytosolic ribonucleoprotein particle that transiently binds to both the ER signal sequence in a nascent protein as well as the large ribosomal subunit, forming a large complex; SRP then targets the nascent protein-ribosome complex to the ER membrane by binding to the SRP receptor on the membrane.

The SRP is made up of six proteins bound to a 300-nucleotide RNA, which acts as a scaffold for the hexamer. One of the SRP proteins (P54) can be chemically cross-linked to ER signal sequences, showing that this is the subunit that binds to the signal sequence in a nascent secretory protein. A region of P54 known as the M domain, containing many methionine and other amino acid residues with hydrophobic side chains, contains a cleft whose inner surface is lined by hydrophobic side chains (Figure 13-5a). The hydrophobic core of the signal peptide binds to this cleft via hydrophobic interactions. Other polypeptides in the SRP interact with the ribosome or are required for protein translocation into the ER lumen.

(a) Ffh signal-sequence-binding domain (related to P54 subunit of SRP)

The SRP brings the nascent chain-ribosome complex to the ER membrane by docking with the SRP receptor, an integral protein of the ER membrane made up of two subunits: an α subunit and a smaller β subunit. Interaction of the SRP/nascent chain/ribosome complex with the SRP receptor is strengthened when both the P54 subunit of SRP and the α subunit of the SRP receptor are bound to GTP. The structure of the P54 subunit of SRP and the SRP receptor α subunit (FtsY), from the archaeobacteria *Thermus aquaticus*, provides insight into how a cycle of GTP binding and hydrolysis can drive the binding and dissociation of these proteins. Figure 13-5b shows that the P54 and FtsY each bound to a single molecule of GTP come together to form a pseudo-symmetrical heterodimer. Neither subunit alone contains a complete active site for the hydrolysis of GTP, but when the two proteins come together, they form two complete active sites that are capable of hydrolyzing both bound GTP molecules.

FOCUS ANIMATION: Synthesis of Secreted and Membrane-Bound Proteins

FIGURE 13-6 Cotranslational translocation. Steps **1, 2**: Once the ER signal sequence emerges from the ribosome, it is bound by a signal-recognition particle (SRP). Step **3**: The SRP delivers the ribosome/nascent polypeptide complex to the SRP receptor in the ER membrane. This interaction is strengthened by binding of GTP to both the SRP and its receptor. Step **4**: Transfer of the ribosome/nascent polypeptide to the translocon leads to opening of this translocation channel and insertion of the signal sequence and adjacent segment of the growing polypeptide into the central pore. Both the SRP and SRP receptor, once dissociated from the translocon, hydrolyze their bound

GTP and then are ready to initiate the insertion of another polypeptide chain. Step **5**: As the polypeptide chain elongates, it passes through the translocon channel into the ER lumen, where the signal sequence is cleaved by signal peptidase and is rapidly degraded. Step **6**: The peptide chain continues to elongate as the mRNA is translated toward the 3' end. Because the ribosome is attached to the translocon, the growing chain is extruded through the translocon into the ER lumen. Steps **7, 8**: Once translation is complete, the ribosome is released, the remainder of the protein is drawn into the ER lumen, the translocon closes, and the protein assumes its native folded conformation.

Figure 13-6 summarizes our current understanding of secretory protein synthesis and the role of the SRP and its receptor in this process. Hydrolysis of the bound GTP accompanies disassembly of the SRP and SRP receptor and, in a manner that is not understood, initiates transfer of the nascent chain and ribosome to a site on the ER membrane, where translocation can take place. After dissociating from each other, SRP and its receptor each release their bound GDP, SRP recycles back to the cytosol, and both are ready to initiate another round of interaction between ribosomes synthesizing nascent secretory proteins and the ER membrane.

Passage of Growing Polypeptides Through the Translocon Is Driven by Translation

Once the SRP and its receptor have targeted a ribosome synthesizing a secretory protein to the ER membrane, the ribosome and nascent chain are rapidly transferred to the **translocon**, a

complex of proteins that forms a channel embedded within the ER membrane. As translation continues, the elongating chain passes directly from the large ribosomal subunit into the central pore of the translocon. The 60S ribosomal subunit is aligned with the pore of the translocon in such a way that the growing chain is never exposed to the cytoplasm and is prevented from folding until it reaches the ER lumen (see Figure 13-6).

The translocon was first identified by mutations in the yeast gene encoding Sec61 α , which caused a block in the translocation of secretory proteins into the lumen of the ER. Subsequently, three proteins called the *Sec61 complex* were found to form the mammalian translocon: Sec61 α , an integral membrane protein with 10 membrane-spanning α helices, and two smaller proteins, termed Sec61 β and Sec61 γ . Chemical cross-linking experiments—in which amino acid side chains from a nascent secretory protein can become covalently attached to the Sec61 α subunit—demonstrated that

EXPERIMENTAL FIGURE 13-7 Sec61 α is a translocon component. Cross-linking experiments show that Sec61 α is a translocon component that contacts nascent secretory proteins as they pass into the ER lumen. An mRNA encoding the N-terminal 70 amino acids of the secreted protein prolactin was translated in a cell-free system containing microsomes (see Figure 13-4b). The mRNA lacked a chain-termination codon and contained one lysine codon, near the middle of the sequence. The reactions contained a chemically modified lysyl-tRNA in which a light-activated cross-linking reagent was attached to the lysine side chain. Although the entire mRNA was translated, the completed polypeptide could not be released from the ribosome without a chain-termination codon and thus became “stuck” crossing the ER membrane. The reaction mixtures then were exposed to an intense light, causing the nascent chain to become covalently bound to whatever proteins were near it in the translocon. When the experiment was performed using microsomes from mammalian cells, the nascent chain became covalently linked to Sec61 α . Different versions of the prolactin mRNA were created so that the modified lysine residue would be placed at different distances from the ribosome; cross-linking to Sec61 α was observed only when the modified lysine was positioned within the translocation channel. [Adapted from T. A. Rapoport, 1992, *Science* **258**:931, and D. Görlich and T. A. Rapoport, 1993, *Cell* **75**:615.]

the translocating polypeptide chain comes into contact with the Sec61 α protein, confirming its identity as the translocon pore (Figure 13-7).

When microsomes in the cell-free translocation system were replaced with reconstituted phospholipid vesicles containing only the SRP receptor and Sec61 complex, nascent secretory protein was translocated from its SRP/ribosome complex into the vesicles. This finding indicates that the SRP receptor and the Sec61 complex are the only ER-membrane proteins that are absolutely required for translocation. Because neither of these can hydrolyze ATP or otherwise provide energy to drive the translocation, the energy derived from chain

elongation at the ribosome appears to be sufficient to push the polypeptide chain across the membrane in one direction.

The translocon must be able to allow passage of a wide variety of polypeptide sequences while remaining sealed to small molecules such as ATP, in order to maintain the permeability barrier of the ER membrane. Furthermore, there must be some way to regulate the translocon so that it is closed in its default state, opening only when a ribosome-nascent chain complex is bound. A high-resolution structure of the Sec61 complex from archaeobacteria shows how the translocon preserves the integrity of the membrane (Figure 13-8). The 10 transmembrane helices of Sec61 α form a central channel through which the translocating peptide chain passes. A constriction in the middle of the central pore is lined with hydrophobic isoleucine residues that in effect form a gasket around the translocating peptide. The structural model of the Sec61 complex, which was isolated without a translocating peptide and therefore is presumed to be in a closed conformation, reveals a short helical peptide plugging the central channel. Biochemical studies of the Sec61 complex have shown that, in the absence of a translocating polypeptide, the peptide that forms the plug effectively seals the translocon to prevent passage of ions and small molecules. Once a translocating peptide enters the channel, the plug peptide swings away to allow translocation to proceed.

As the growing polypeptide chain enters the lumen of the ER, the signal sequence is cleaved by *signal peptidase*, which is a transmembrane ER protein associated with the translocon (see Figure 13-6, step 5). Signal peptidase recognizes a sequence on the C-terminal side of the hydrophobic core of the signal peptide and cleaves the chain specifically at this sequence once it has emerged into the luminal space of the ER. After the signal sequence has been cleaved, the growing polypeptide moves through the translocon into the ER lumen. The translocon remains open until translation is completed and the entire polypeptide chain has moved into the ER lumen. After translocation is complete, the plug helix returns to the pore to reseal the translocon channel.

ATP Hydrolysis Powers Post-translational Translocation of Some Secretory Proteins in Yeast

In most eukaryotes, secretory proteins enter the ER by cotranslational translocation. In yeast, however, some secretory proteins enter the ER lumen after translation has been completed. In such *post-translational translocation*, the translocating protein passes through the same Sec61 translocon that is used in cotranslational translocation. However, the SRP and SRP receptor are not involved in post-translational translocation, and in such cases a direct interaction between the translocon and the signal sequence of the completed protein appears to be sufficient for targeting to the ER membrane. In addition, the driving force for unidirectional translocation across the ER membrane is provided by an additional protein complex known as the *Sec63 complex*

VIDEO: Three-Dimensional Model of a Protein Translocation Channel

EXPERIMENTAL FIGURE 13-8 Structure of a bacterial Sec61 complex

The structure of the detergent-solubilized Sec61 complex from the archaeobacterium *M. jannaschii* (also known as the SecY complex) was determined by x-ray crystallography. (a) A side view shows the hourglass-shaped channel through the center of the pore. A ring of isoleucine residues at the constricted waist of the pore forms a gasket that keeps the channel sealed to small molecules even as a translocating polypeptide passes through the channel. When no translocating peptide is present, the channel is closed by a short helical plug (red). This plug moves out of the channel during translocation. In this view the front half of protein has been removed to better show the pore. (b) A view looking through the center of the channel shows a region (on the left side) where helices may separate, allowing lateral passage of a hydrophobic transmembrane domain into the lipid bilayer. [Adapted from A. R. Osborne et al., 2005, *Ann. Rev. Cell Dev. Biol.* 21:529.]

and a member of the Hsc70 family of **molecular chaperones** known as *BiP* (see Chapter 3 for further discussion of molecular chaperones). The tetrameric Sec63 complex is embedded in the ER membrane in the vicinity of the translocon, whereas BiP is within the ER lumen. Like other members of the Hsc70 family, BiP has a peptide-binding domain and an ATPase domain. These chaperones bind and stabilize unfolded or partially folded proteins (see Figure 3-16).

The current model for post-translational translocation of a protein into the ER is outlined in Figure 13-9. Once the N-terminal segment of the protein enters the ER lumen, signal peptidase cleaves the signal sequence just as in cotranslational translocation (step 1). Interaction of BiP•ATP with the luminal portion of the Sec63 complex causes hydrolysis of the bound ATP, producing a conformational change in BiP that promotes its binding to an exposed polypeptide chain (step 2). Since the Sec63 complex is located near the translocon, BiP is thus activated at sites where nascent polypeptides can enter the ER. Certain experiments suggest that, in the absence of binding to BiP, an unfolded polypeptide slides back and forth within the translocon channel. Such random sliding motions rarely result in the entire polypeptide's crossing the ER membrane. Binding of a molecule of BiP•ADP to the luminal portion of the polypeptide prevents backsliding of the polypeptide out of the ER. As further inward random sliding exposes more of the polypeptide on the luminal side of the ER membrane, successive binding of BiP•ADP molecules to the polypeptide chain acts as a ratchet, ultimately drawing the entire polypeptide into the ER within a few seconds (steps 3 and 4). On a slower time scale, the BiP molecules spontaneously exchange their bound ADP for ATP, leading to release of the polypeptide, which can then fold into its native conformation (steps 5 and 5). The recycled BiP•ATP then is ready for another interaction with Sec63. BiP and the Sec63 complex are also required for cotranslational translocation. The details of

their role in this process are not well understood, but they are thought to act at an early stage of the process, such as threading the signal peptide into the pore of the translocon.

The overall reaction carried out by BiP is an important example of how the chemical energy released by the hydrolysis of ATP can power the mechanical movement of a protein across a membrane. Bacterial cells also use an ATP-driven process for translocating completed proteins across the plasma membrane—in this case to be released from the cell. In bacteria the driving force for translocation comes from a cytosolic ATPase known as the SecA protein. SecA binds to the cytoplasmic side of the translocon and hydrolyzes cytosolic ATP. By a mechanism that resembles the needle on a sewing machine, the SecA protein pushes segments of the polypeptide through the membrane in a mechanical cycle coupled to the hydrolysis of ATP.

As we will see, translocation of proteins across other eukaryotic organelle membranes, such as those of mitochondria and chloroplasts, also typically occurs by post-translational translocation. This explains why ribosomes are not found bound to these other organelles, as they are to the rough ER.

FIGURE 13-9 Post-translational translocation. This mechanism is fairly common in yeast and probably occurs occasionally in higher eukaryotes. Small arrows inside the translocon represent random sliding of the translocating polypeptide inward and outward. Successive binding of BiP-ADP to entering segments of the polypeptide prevents the chain from sliding out toward the cytosol. [See K. E. Matlack et al., 1997, *Science* 277:938.]

KEY CONCEPTS of Section 13.1

Targeting Proteins to and Across the ER Membrane

- Synthesis of secreted proteins, integral plasma-membrane proteins, and proteins destined for the ER, Golgi complex, or lysosome begins on cytosolic ribosomes, which become attached to the membrane of the ER, forming the rough ER (see Figure 13-1, *left*).
- The ER signal sequence on a nascent secretory protein consists of a segment of hydrophobic amino acids located at the N-terminus.
- In cotranslational translocation, the signal-recognition particle (SRP) first recognizes and binds the ER signal sequence on a nascent secretory protein and in turn is bound by an SRP receptor on the ER membrane, thereby targeting the ribosome/nascent chain complex to the ER.
- The SRP and SRP receptor then mediate insertion of the nascent secretory protein into the translocon (Sec61 complex). Hydrolysis of two molecules of GTP by the SRP and its receptor cause the dissociation of SRP (see Figures 13-5 and 13-6). As the ribosome attached to the translocon continues

translation, the unfolded protein chain is extruded into the ER lumen. No additional energy is required for translocation.

- The translocon contains a central channel lined with hydrophobic residues that allows transit of an unfolded protein chain while remaining sealed to ions and small hydrophilic molecules. In addition, the channel is gated so that it is open only when a polypeptide is being translocated.
- In post-translational translocation, a completed secretory protein is targeted to the ER membrane by interaction of the signal sequence with the translocon. The polypeptide chain is then pulled into the ER by a ratcheting mechanism that requires ATP hydrolysis by the chaperone BiP, which stabilizes the entering polypeptide (see Figure 13-9). In bacteria, the driving force for post-translational translocation comes from SecA, a cytosolic ATPase that pushes polypeptides through the translocon channel.
- In both cotranslational and post-translational translocation, a signal peptidase in the ER membrane cleaves the ER signal sequence from a secretory protein soon after the N-terminus enters the lumen.

13.2 Insertion of Membrane Proteins into the ER

In previous chapters we have encountered many of the vast array of integral (transmembrane) proteins that are present throughout the cell. Each such protein has a unique orientation with respect to the membrane's phospholipid bilayer. Integral membrane proteins located in the ER, Golgi, and lysosomes, and also proteins in the plasma membrane, which are all synthesized on the rough ER, remain embedded in the membrane in their unique orientation as they move to their final destinations along the same pathway followed by soluble secretory proteins (see Figure 13-1, *left*). During this transport, the orientation of a membrane protein is preserved; that is, the same segments of the protein always face the cytosol, whereas other segments always face in the opposite direction. Thus the final orientation of these membrane proteins is established during their biosynthesis on the ER membrane. In this section, we first see how integral proteins can interact with membranes and then examine how several types of sequences, known collectively as **topogenic sequences**, direct the membrane insertion and orientation of various classes of integral proteins. These processes occur via modifications of the basic mechanism used to translocate soluble secretory proteins across the ER membrane.

Several Topological Classes of Integral Membrane Proteins Are Synthesized on the ER

The **topology** of a membrane protein refers to the number of times that its polypeptide chain spans the membrane and the orientation of these membrane-spanning segments within the membrane. The key elements of a protein that determine its topology are membrane-spanning segments themselves, which usually are α helices containing 20–25 hydrophobic amino acids that contribute to energetically favorable interactions within the hydrophobic interior of the phospholipid bilayer.

Most integral membrane proteins fall into one of the five topological classes illustrated in Figure 13-10. Topological classes I, II, III, and tail-anchored proteins comprise **single-pass** proteins, which have only one membrane-spanning α -helical segment. Type I proteins have a cleaved N-terminal ER signal sequence and are anchored in the membrane with their hydrophilic N-terminal region on the luminal face (also known as the exoplasmic face) and their hydrophilic C-terminal region on the cytosolic face. Type II proteins do not contain a cleavable ER signal sequence and are oriented with their hydrophilic N-terminal region on the cytosolic face and their hydrophilic C-terminal region on the exoplasmic face (i.e., opposite to type I proteins). Type III proteins have a hydrophobic membrane-spanning segment at their N-terminus and thus have the same orientation as type I proteins but do not contain

FIGURE 13-10 ER membrane proteins. Five topological classes of integral membrane proteins are synthesized on the rough ER as well as a sixth type tethered to the membrane by a phospholipid anchor. Membrane proteins are classified by their orientation in the membrane and the types of signals they contain to direct them there. For the integral membrane proteins, hydrophobic segments of the protein chain form α helices embedded in the membrane bilayer; the regions outside the membrane are hydrophilic and fold into various conformations. All

type IV proteins have multiple transmembrane α helices. The type IV topology depicted here corresponds to that of G protein-coupled receptors: seven α helices, the N-terminus on the exoplasmic side of the membrane, and the C-terminus on the cytosolic side. Other type IV proteins may have a different number of helices and various orientations of the N-terminus and C-terminus. [See E. Hartmann et al., 1989, *Proc. Nat'l Acad. Sci. USA* **86**:5786, and C. A. Brown and S. D. Black, 1989, *J. Biol. Chem.* **264**:4442.]

a cleavable signal sequence. Finally, tail-anchored proteins have a hydrophobic segment at their C-terminus that spans the membrane. These different topologies reflect distinct mechanisms used by the cell to establish the membrane orientation of transmembrane segments, as discussed in the next section.

The proteins forming topological class IV contain two or more membrane-spanning segments and are sometimes called *multipass* proteins. For example, many of the membrane transport proteins discussed in Chapter 11 and the numerous G protein-coupled receptors covered in Chapter 15 belong to this class. A final type of membrane protein lacks a hydrophobic membrane-spanning segment altogether; instead, these proteins are linked to an amphipathic phospholipid anchor that is embedded in the membrane (Figure 13-10, *right*).

Internal Stop-Transfer and Signal-Anchor Sequences Determine Topology of Single-Pass Proteins

We begin our discussion of how membrane protein topology is determined with the membrane insertion of integral proteins that contain a single, hydrophobic membrane-spanning segment. Two sequences are involved in targeting and orienting type I proteins in the ER membrane, whereas type II and type III proteins contain a single, internal topogenic sequence. As we will see, there are three main types of topogenic

sequences that are used to direct proteins to the ER membrane and to orient them within it. We have already introduced one, the N-terminal signal sequence. The other two, introduced here, are internal sequences known as *stop-transfer anchor sequences* and *signal-anchor sequences*. Unlike signal sequences, the two types of internal topogenic sequences end up in the mature protein as membrane-spanning segments. However, the two types of internal topogenic sequences differ in their final orientation in the membrane.

Type I Proteins All type I transmembrane proteins possess an N-terminal signal sequence that targets them to the ER as well as an internal hydrophobic sequence that becomes the membrane-spanning α helix. The N-terminal signal sequence on a nascent type I protein, like that of a soluble secretory protein, initiates cotranslational translocation of the protein through the combined action of the SRP and SRP receptor. Once the N-terminus of the growing polypeptide enters the lumen of the ER, the signal sequence is cleaved, and the growing chain continues to be extruded across the ER membrane. However, unlike the case with soluble secretory proteins, when the sequence of approximately 22 hydrophobic amino acids that will become a transmembrane domain of the nascent chain enters the translocon, it stops transfer of the protein through the channel (Figure 13-11). The Sec61 complex is then able to open like a clamshell, allowing the hydrophobic

FIGURE 13-11 Positioning type I single-pass proteins. Step **1**: After the ribosome/nascent chain complex becomes associated with a translocon in the ER membrane, the N-terminal signal sequence is cleaved. This process occurs by the same mechanism as the one for soluble secretory proteins (see Figure 13-6). Steps **2**, **3**: The chain is elongated until the hydrophobic stop-transfer anchor sequence is synthesized and enters the translocon, where it prevents the nascent chain from extruding farther into the ER lumen. Step **4**: The stop-

transfer anchor sequence moves laterally between the translocon subunits and becomes anchored in the phospholipid bilayer. At this time, the translocon probably closes. Step **5**: As synthesis continues, the elongating chain may loop out into the cytosol through the small space between the ribosome and translocon. Step **6**: When synthesis is complete, the ribosomal subunits are released into the cytosol, leaving the protein free to diffuse in the membrane. [See H. Do et al., 1996, *Cell* **85**:369, and W. Mothes et al., 1997, *Cell* **89**:523.]

transmembrane segment of the translocating peptide to move laterally between the protein domains constituting the translocon wall (see Figure 13-8). When the peptide exits the translocon in this manner, it becomes anchored in the phospholipid bilayer of the membrane. Because of the dual function of such a sequence to both stop passage of the polypeptide chain through the translocon and to become a hydrophobic transmembrane segment in the membrane bilayer, it is called a *stop-transfer anchor sequence*.

Once translocation is interrupted, translation continues at the ribosome, which is still anchored to the now unoccupied and closed translocon. As the C-terminus of the protein chain is synthesized, it loops out on the cytosolic side of the membrane. When translation is completed, the ribosome is released from the translocon and the C-terminus of the newly synthesized type I protein remains in the cytosol.

Support for this mechanism has come from studies in which cDNAs encoding various mutant receptors for human growth hormone (HGH) are expressed in cultured mammalian cells. The wild-type HGH receptor, a typical type I protein, is transported normally to the plasma membrane. However, a mutant receptor that has charged residues inserted into the

single α -helical membrane-spanning segment or that is missing most of this segment is translocated entirely into the ER lumen and is eventually secreted from the cell as a soluble protein. These kinds of experiments establish that the hydrophobic membrane-spanning α helix of the HGH receptor and of other type I proteins functions both as a stop-transfer sequence and as a membrane anchor that prevents the C-terminus of the protein from crossing the ER membrane.

Type II and Type III Proteins Unlike type I proteins, type II and type III proteins lack a cleavable N-terminal ER signal sequence. Instead, both possess a single internal hydrophobic *signal-anchor sequence* that functions as both an ER signal sequence and a membrane-anchor sequence. Recall that type II and type III proteins have opposite orientations in the membrane (see Figure 13-10); this difference depends on the orientation that their respective signal-anchor sequences assume within the translocon. The internal signal-anchor sequence in type II proteins directs insertion of the nascent chain into the ER membrane so that the N-terminus of the chain faces the cytosol, using the same SRP-dependent mechanism described for signal sequences (Figure 13-12a). However, the internal

FIGURE 13-12 Positioning type II and type III single-pass proteins. (a) Type II proteins. Step 1: After the internal signal-anchor sequence is synthesized on a cytosolic ribosome, it is bound by an SRP (not shown), which directs the ribosome/nascent chain complex to the ER membrane. This is similar to targeting of soluble secretory proteins except that the hydrophobic signal sequence is not located at the N-terminus and is not subsequently cleaved. The nascent chain becomes oriented in the translocon with its N-terminal portion toward the cytosol. This orientation is believed to be mediated by the positively charged residues shown N-terminal to the signal-anchor sequence. Step 2: As the chain is elongated and extruded into the lumen, the internal signal-anchor moves laterally out of the translocon

and anchors the chain in the phospholipid bilayer. Step 2: Once protein synthesis is completed, the C-terminus of the polypeptide is released into the lumen, and the ribosomal subunits are released into the cytosol. (b) Type III proteins. Step 1: Assembly is by a similar pathway to that of type II proteins except that positively charged residues on the C-terminal side of the signal-anchor sequence cause the transmembrane segment to be oriented within the translocon with its C-terminal portion oriented to the cytosol and the N-terminal side of the protein in the ER lumen. Steps 2, 3: Chain elongation of the C-terminal portion of the protein is completed in the cytosol, and ribosomal subunits are released. [See M. Spiess and H. F. Lodish, 1986, *Cell* 44:177, and H. Do et al., 1996, *Cell* 85:369.]

signal-anchor sequence is *not* cleaved and moves laterally between the protein domains of the translocon wall into the phospholipid bilayer, where it functions as a membrane anchor. As elongation continues, the C-terminal region of the growing chain is extruded through the translocon into the ER lumen by cotranslational translocation.

In the case of type III proteins, the signal-anchor sequence, which is located near the N-terminus, inserts the nascent chain into the ER membrane with its N-terminus facing the lumen, in the opposite orientation of the signal anchor in type II proteins. The signal-anchor sequence of type III proteins also functions like a stop-transfer sequence and prevents further extrusion of the nascent chain into the ER lumen (Figure 13-12b). Continued elongation of the chain C-terminal to the signal-anchor/stop-transfer sequence proceeds as it does for type I proteins, with the hydrophobic sequence moving laterally between the translocon subunits to anchor the polypeptide in the ER membrane (see Figure 13-11).

One of the features of signal-anchor sequences that appears to determine their insertion orientation is a high density of positively charged amino acids adjacent to one end of the hydrophobic segment. These positively charged residues tend to remain on the cytosolic side of the membrane, not traversing the membrane into the ER lumen. Thus the position of the charged residues dictates the orientation of the signal-anchor sequence within the translocon as well as whether the rest of the polypeptide chain continues to pass into the ER lumen: type II proteins tend to have positively charged residues on the N-terminal side of their signal-anchor sequence, orienting the N-terminus in the cytosol and allowing passage of the C-terminal side into the ER (Figure 13-12a), whereas type III proteins tend to have positively charged residues on the C-terminal side of their signal-anchor sequence, inserting the N-terminus into the translocon and restricting the C-terminus to the cytosol (Figure 13-12b).

A striking experimental demonstration of the importance of the flanking charge in determining membrane orientation is provided by neuraminidase, a type II protein in the surface

coat of influenza virus. Three arginine residues are located just N-terminal to the internal signal-anchor sequence in neuraminidase. Mutation of these three positively charged residues to negatively charged glutamate residues causes neuraminidase to acquire the reverse orientation. Similar experiments have shown that other proteins, with either type II or type III orientation, can be made to “flip” their orientation in the ER membrane by mutating charged residues that flank the internal signal-anchor segment.

Tail-Anchored Proteins For all topological classes of proteins we have considered so far, membrane insertion begins when SRP recognizes a hydrophobic topogenic peptide as it emerges from the ribosome. Recognition of tail-anchored proteins, which have a single hydrophobic topogenic sequence at the C-terminus, present a unique challenge since the hydrophobic C-terminus only becomes available for recognition after completion of translation and the protein has been released from the ribosome. Insertion of tail-anchored proteins into the ER membrane does not employ SRP, SRP receptor, or the translocon, but instead depends on a pathway dedicated for this purpose as depicted in Figure 13-13. Targeting of tail-anchored proteins involves an ATPase known as Get3, which binds to the C-terminal hydrophobic segment of tail-anchored proteins. The complex of Get3 bound to a tail-anchored protein is recruited to the ER by a dimeric integral membrane receptor known as Get1/Get2, and the tail-anchored protein is released from Get3 for insertion into the membrane. Insertion of tail-anchored protein into the ER membranes by Get proteins shares fundamental mechanistic similarities to the targeting of signal sequence-bearing proteins to the ER by SRP and SRP receptor. Two major differences between the two targeting processes are that, after release from Get3, tail-anchored proteins may be inserted directly into the membrane bilayer, whereas SRP transfers a signal sequence to the translocon, and that Get3 couples targeting and transfer of tail-anchored proteins to ATP hydrolysis, whereas SRP couples secretory protein targeting to GTP hydrolysis.

FIGURE 13-13 Insertion of tail-anchored proteins. For C-terminal tail-anchored proteins the hydrophobic C-terminus is not available for membrane insertion until protein synthesis is complete and the protein has been released from the ribosome. Step 1: Get3 in an ATP-bound state binds to the hydrophobic C-terminal tail. This binding reaction is facilitated by a complex of three proteins, Sgt2, Get4, and Get5, which sequester the hydrophobic C-terminal tail before transferring it to Get3-ATP (not shown). Step 2: The ternary complex Get3-ATP bound to the C-terminal tail docks onto the Get1 and Get2 proteins, which are embedded in the ER membrane. Step 3: In succession, ATP is hydrolyzed and ADP is released from Get3. At the same time, the hydrophobic C-terminal tail is released from Get3 and becomes embedded in the ER membrane. Step 4: Get3 binds to ATP and Get3-ATP is released from the complex of Get1 and Get2 in a soluble form, ready for another round of binding to a hydrophobic C-terminal tail.

Multipass Proteins Have Multiple Internal Topogenic Sequences

Figure 13-14 summarizes the arrangements of topogenic sequences in single-pass and multipass transmembrane proteins. In multipass (type IV) proteins, each of the membrane-spanning α helices acts as a topogenic sequence in the ways that we have already discussed: they can act to direct the protein to the ER, to anchor the protein in the ER membrane, or to stop transfer of the protein through the membrane. Multipass proteins fall into one of two types, depending on whether the N-terminus extends into the cytosol or the exoplasmic space (e.g., the ER lumen, cell exterior). This N-terminal topology usually is determined by the hydrophobic segment closest to the N-terminus and the charge of the sequences flanking it. If a type IV protein has an *even* number of transmembrane α helices, both its N-terminus and C-terminus will be oriented toward the same side of the membrane (Figure 13-14d). Conversely, if a type IV protein has an *odd* number of α helices, its two ends will have opposite orientations (Figure 13-14e).

Type IV Proteins with N-Terminus in Cytosol Among the multipass proteins whose N-terminus extends into the cytosol are the various glucose transporters (GLUTs) and most ion-channel proteins, discussed in Chapter 11. In these proteins, the hydrophobic segment closest to the N-terminus

initiates insertion of the nascent chain into the ER membrane with the N-terminus oriented toward the cytosol; thus this α -helical segment functions like the internal signal-anchor sequence of a type II protein (see Figure 13-12a). As the nascent chain following the first α helix elongates, it moves through the translocon until the second hydrophobic α helix is formed. This helix prevents further extrusion of the nascent chain through the translocon; thus its function is similar to that of the stop-transfer anchor sequence in a type I protein (see Figure 13-11).

After synthesis of the first two transmembrane α helices, both ends of the nascent chain face the cytosol and the loop between them extends into the ER lumen. The C-terminus of the nascent chain then continues to grow into the cytosol, as it does in synthesis of type I and type III proteins. According to this mechanism, the third α helix acts as another type II signal-anchor sequence and the fourth as another stop-transfer anchor sequence (Figure 13-14d). Apparently, once the first topogenic sequence of a multipass polypeptide initiates association with the translocon, the ribosome remains attached to the translocon, and topogenic sequences that subsequently emerge from the ribosome are threaded into the translocon without the need for the SRP and the SRP receptor.

Experiments that use recombinant DNA techniques to exchange hydrophobic α helices have provided insight into the functioning of the topogenic sequences in type IV-A multipass proteins. These experiments indicate that the order of

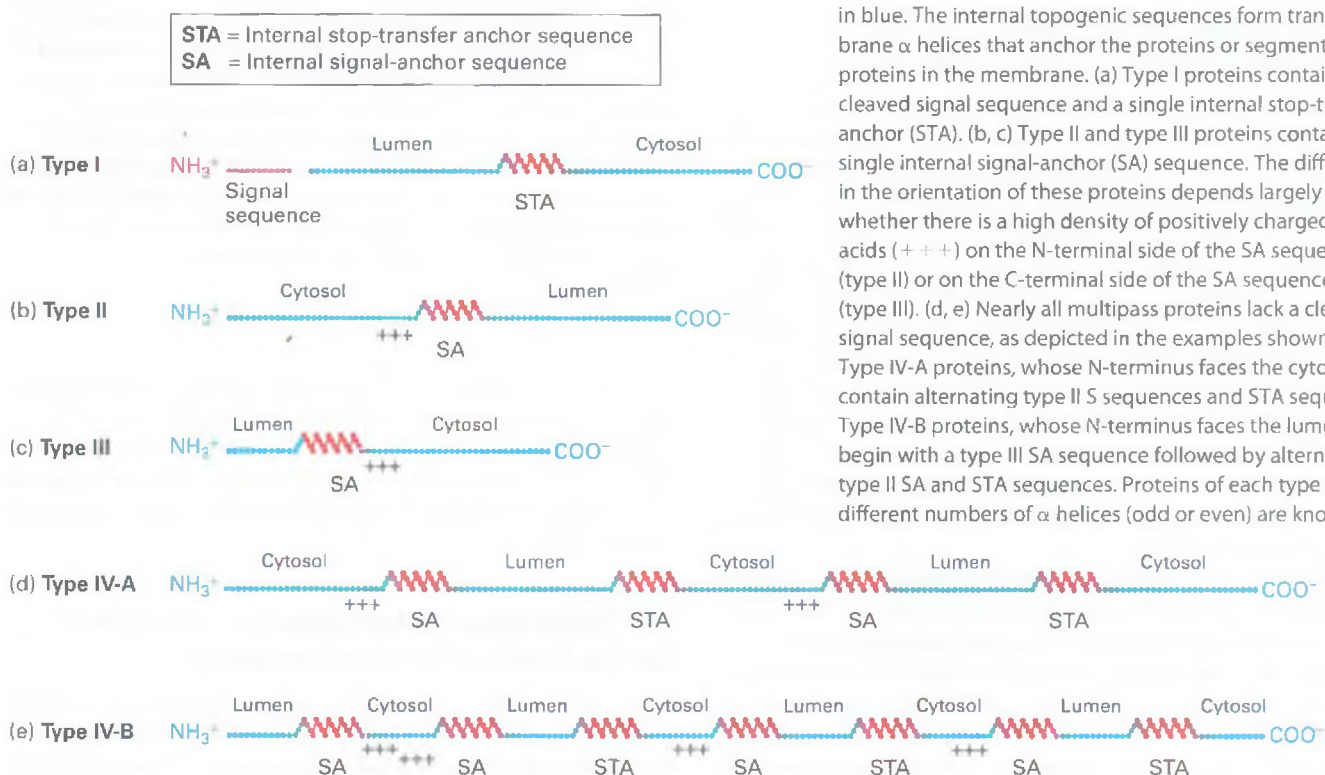

FIGURE 13-14 Topogenic sequences determine orientation of ER membrane proteins. Topogenic sequences are shown in red; soluble, hydrophilic portions in blue. The internal topogenic sequences form transmembrane α helices that anchor the proteins or segments of proteins in the membrane. (a) Type I proteins contain a cleaved signal sequence and a single internal stop-transfer anchor (STA). (b, c) Type II and type III proteins contain a single internal signal-anchor (SA) sequence. The difference in the orientation of these proteins depends largely on whether there is a high density of positively charged amino acids (+++) on the N-terminal side of the SA sequence (type II) or on the C-terminal side of the SA sequence (type III). (d, e) Nearly all multipass proteins lack a cleavable signal sequence, as depicted in the examples shown here. Type IV-A proteins, whose N-terminus faces the cytosol, contain alternating type II SA sequences and STA sequences. Type IV-B proteins, whose N-terminus faces the lumen, begin with a type III SA sequence followed by alternating type II SA and STA sequences. Proteins of each type with different numbers of α helices (odd or even) are known.

the hydrophobic α helices relative to each other in the growing chain largely determines whether a given helix functions as a signal-anchor sequence or a stop-transfer anchor sequence. Other than its hydrophobicity, the specific amino acid sequence of a particular helix has little bearing on its function. Thus the first N-terminal α helix and the subsequent odd-numbered ones function as signal-anchor sequences, whereas the intervening even-numbered helices function as stop-transfer anchor sequences. This odd-even relationship among signal-anchor and stop-transfer anchor sequences is dictated by the fact that the transmembrane α helices assume alternating orientations as a multipass protein is woven back and forth across the membrane; signal anchor sequences are oriented with their N-termini toward the cytoplasmic side of the bilayer, whereas stop-transfer sequences have their N-termini oriented toward the exoplasmic side of the bilayer.

Type IV Proteins with N-Terminus in the Exoplasmic Space The large family of G protein-coupled receptors, all of which contain seven transmembrane α helices, constitute the most numerous type IV-B proteins, whose N-terminus extends into the exoplasmic space. In these proteins, the hydrophobic α helix closest to the N-terminus often is followed by a cluster of positively charged amino acids, similar to a type III signal-anchor sequence (see Figure 13-12b). As a result, the first α helix inserts the nascent chain into the translocon with the N-terminus extending into the lumen (see Figure 13-14c). As the chain is elongated, it is inserted into the ER membrane by alternating type II signal-anchor sequences and stop-transfer sequences, as just described for type IV-A proteins.

A Phospholipid Anchor Tethers Some Cell-Surface Proteins to the Membrane

Some cell-surface proteins are anchored to the phospholipid bilayer not by a sequence of hydrophobic amino acids but by a covalently attached amphipathic molecule, *glycosylphosphatidylinositol* (GPI) (Figure 13-15a and Chapter 10). These proteins are synthesized and initially anchored to the ER membrane exactly like type I transmembrane proteins, with a cleaved N-terminal signal sequence and an internal stop-transfer anchor sequence directing the process (see Figure 13-11). However, a short sequence of amino acids in the luminal domain, adjacent to the membrane-spanning domain, is recognized by a transamidase located within the ER membrane. This enzyme simultaneously cleaves off the original stop-transfer anchor sequence and transfers the luminal portion of the protein to a preformed GPI anchor in the membrane (Figure 13-15b).

Why change one type of membrane anchor for another? Attachment of the GPI anchor, which results in removal of the cytosol-facing hydrophilic domain from the protein, can have several consequences. Proteins with GPI anchors, for example, can diffuse relatively rapidly in the plane of the phospholipid bilayer membrane. In contrast, many proteins anchored by membrane-spanning α helices are impeded

FIGURE 13-15 GPI-anchored proteins. (a) Structure of a glycosylphosphatidylinositol (GPI) from yeast. The hydrophobic portion of the molecule is composed of fatty acyl chains, whereas the polar (hydrophilic) portion of the molecule is composed of carbohydrate residues and phosphate groups. In other organisms, both the length of the acyl chains and the carbohydrate moieties may vary somewhat from the structure shown. (b) Formation of GPI-anchored proteins in the ER membrane. The protein is synthesized and initially inserted into the ER membrane as shown in Figure 13-11. A specific transamidase simultaneously cleaves the precursor protein within the exoplasmic-facing domain, near the stop-transfer anchor sequence (red), and transfers the carboxyl group of the new C-terminus to the terminal amino group of a preformed GPI anchor. [See C. Abeijon and C. B. Hirschberg, 1992, *Trends Biochem. Sci.* 17:32, and K. Kodukula et al., 1992, *Proc. Nat'l Acad. Sci. USA* 89:4982.]

from moving laterally in the membrane because their cytosol-facing segments interact with the cytoskeleton. In addition, the GPI anchor targets the attached protein to the apical domain of the plasma membrane (instead of the basolateral domain) in certain polarized epithelial cells, as we discuss in Chapter 14.

The Topology of a Membrane Protein Often Can Be Deduced from Its Sequence

As we have seen, various topogenic sequences in integral membrane proteins synthesized on the ER govern interaction of the nascent chain with the translocon. When scientists

begin to study a protein of unknown function, the identification of potential topogenic sequences within the corresponding gene sequence can provide important clues about the protein's topological class and function. Suppose, for example, that the gene for a protein known to be required for a cell-to-cell signaling pathway contains nucleotide sequences that encode an apparent N-terminal signal sequence and an internal hydrophobic sequence. These findings suggest that the protein is a type I integral membrane protein and therefore may be a cell-surface receptor for an extracellular ligand. Furthermore, the implied type I topology suggests that the N-terminal segment that lies between the signal sequence and the internal hydrophobic sequence constitutes the extracellular domain which would likely have a part in ligand binding, whereas the C-terminal segment that lies after the internal hydrophobic sequence would likely be cytosolic and may have a part in intracellular signalling.

Identification of topogenic sequences requires a way to scan sequence databases for segments that are sufficiently hydrophobic to be either a signal sequence or a transmembrane anchor sequence. Topogenic sequences can often be identified with the aid of computer programs that generate a *hydropathy profile* for the protein of interest. The first step is to assign a value known as the *hydropathic index* to each amino acid in the protein. By convention, hydrophobic amino acids are assigned positive values and hydrophilic amino acids negative values. Although different scales for the hydropathic index exist, all assign the most positive values to amino acids with side chains made up of mostly hydrocarbon residues (e.g., phenylalanine and methionine) and the most negative values to charged amino acids (e.g., arginine and aspartate). The second

step is to identify longer segments of sufficient overall hydrophobicity to be N-terminal signal sequences or internal stop-transfer sequences and signal-anchor sequences. To accomplish this, the total hydropathic index for each successive segment of 20 consecutive amino acids is calculated along the entire length of the protein. Plots of these calculated values against position in the amino acid sequence yield a hydropathy profile.

Figure 13-16 shows the hydropathy profiles for three different membrane proteins. The prominent peaks in such plots identify probable topogenic sequences as well as their position and approximate length. For example, the hydropathy profile of the human growth hormone receptor reveals the presence of both a hydrophobic signal sequence at the extreme N-terminus of the protein and an internal hydrophobic stop-transfer sequence (Figure 13-16a). On the basis of this profile, we can deduce, correctly, that the human growth hormone receptor is a type I integral membrane protein. The hydropathy profile of the asialoglycoprotein receptor, a cell-surface protein that mediates removal of abnormal extracellular glycoproteins, reveals a prominent internal hydrophobic signal-anchor sequence but gives no indication of a hydrophobic N-terminal signal sequence (Figure 13-16b). Thus we can predict that the asialoglycoprotein receptor is a type II or type III membrane protein. The distribution of charged residues on either side of the signal-anchor sequence often can differentiate between these possibilities, since positively charged amino acids flanking a membrane-spanning segment usually are oriented toward the cytosolic face of the membrane. For instance, in the case of the asialoglycoprotein receptor, examination of the residues flanking the signal-anchor sequence reveals that the residues on the N-terminal

EXPERIMENTAL FIGURE 13-16 Hydropathy profiles.

Hydropathy profiles can identify likely topogenic sequences in integral membrane proteins. They are generated by plotting the total hydrophobicity of each segment of 20 contiguous amino acids along the length of a protein. Positive values indicate relatively hydrophobic

portions; negative values, relatively polar portions of the protein. Probable topogenic sequences are marked. The complex profiles for multipass (type IV) proteins, such as GLUT1 in part (c), often must be supplemented with other analyses to determine the topology of these proteins.

side carry a net positive charge, thus correctly predicting that this is a type II protein.

The hydropathy profile of the GLUT1 glucose transporter, a multipass membrane protein, shows the presence of many segments that are sufficiently hydrophobic to be membrane-spanning helices (Figure 13-16c). The complexity of this profile illustrates the difficulty both in unambiguously identifying all the membrane-spanning segments in a multipass protein and in predicting the topology of individual signal-anchor and stop-transfer sequences. More sophisticated computer algorithms have been developed that take into account the presence of positively charged amino acids adjacent to hydrophobic segments as well as the length of and spacing between segments. Using all this information, the best algorithms can predict the complex topology of multipass proteins with an accuracy of greater than 75 percent.

Finally, sequence homology to a known protein may permit accurate prediction of the topology of a newly discovered multipass protein. For example, the genomes of multicellular organisms encode a very large number of multipass proteins with seven transmembrane α helices. The similarities between the sequences of these proteins strongly suggest that all have the same topology as the well-studied G protein-coupled receptors, which have the N-terminus oriented to the exoplasmic side and the C-terminus oriented to the cytosolic side of the membrane.

KEY CONCEPTS of Section 13.2

Insertion of Membrane Proteins into the ER

- Integral membrane proteins synthesized on the rough ER fall into five topological classes as well as a lipid-linked type (see Figure 13-10).
- Topogenic sequences—N-terminal signal sequences, internal stop-transfer anchor sequences, and internal signal-anchor sequences—direct the insertion and orientation of nascent proteins within the ER membrane. This orientation is retained during transport of the completed membrane protein to its final destination—e.g., the plasma membrane.
- Single-pass membrane proteins contain one or two topogenic sequences. In multipass membrane proteins, each α -helical segment can function as an internal topogenic sequence, depending on its location in the polypeptide chain and the presence of adjacent positively charged residues (see Figure 13-14).
- Some cell-surface proteins are initially synthesized as type I proteins on the ER and then are cleaved with their luminal domain transferred to a GPI anchor (see Figure 13-15).
- The topology of membrane proteins can often be correctly predicted by computer programs that identify hydrophobic topogenic segments within the amino acid sequence and generate hydropathy profiles (see Figure 13-16).

13.3 Protein Modifications, Folding, and Quality Control in the ER

Membrane and soluble secretory proteins synthesized on the rough ER undergo four principal modifications before they reach their final destinations: (1) covalent addition and processing of carbohydrates (*glycosylation*) in the ER and Golgi, (2) formation of disulfide bonds in the ER, (3) proper folding of polypeptide chains and assembly of multisubunit proteins in the ER, and (4) specific proteolytic cleavages in the ER, Golgi, and secretory vesicles. Generally speaking, these modifications promote folding of secretory proteins into their native structures and add structural stability to proteins exposed to the extracellular environment. Modifications such as glycosylation also allow the cell to produce a vast array of chemically distinct molecules at the cell surface that are the basis of specific molecular interactions used in cell-to-cell adhesion and communication.

One or more carbohydrate chains are added to the majority of proteins that are synthesized on the rough ER; indeed, glycosylation is the principal chemical modification to most of these proteins. Proteins with attached carbohydrates are known as **glycoproteins**. Carbohydrate chains in glycoproteins attached to the hydroxyl ($-\text{OH}$) group in serine and threonine residues are referred to as **O-linked oligosaccharides**, and carbohydrate chains attached to the amide nitrogen of asparagine are referred to as **N-linked oligosaccharides**. The various types of O-linked oligosaccharides include the mucin-type O-linked chains (named after abundant glycoproteins found in mucus) and the carbohydrate modifications on proteoglycans described in Chapter 20. O-linked chains typically contain only one to four sugar residues, which are added to proteins by enzymes known as glycosyltransferases, located in the lumen of the Golgi complex. The more common N-linked oligosaccharides are larger and more complex, containing several branches. In this section we focus on N-linked oligosaccharides, whose initial synthesis occurs in the ER. After the initial N-glycosylation of a protein in the ER, the oligosaccharide chain is modified in the ER and commonly in the Golgi as well.

Disulfide bond formation, protein folding, and assembly of multimeric proteins, which take place exclusively in the rough ER, also are discussed in this section. Only properly folded and assembled proteins are transported from the rough ER to the Golgi complex and ultimately to the cell surface or other final destination through the secretory pathway. Unfolded, misfolded, or partly folded and assembled proteins are selectively retained in the rough ER and then can be degraded. We consider several features of such “quality control” in the latter part of this section.

As discussed previously, N-terminal ER signal sequences are cleaved from soluble secretory proteins and type I membrane proteins in the ER. Some proteins also undergo other specific proteolytic cleavages in the Golgi complex or secretory vesicles. We cover these cleavages, as well as carbohydrate modifications that occur primarily or exclusively in the Golgi complex, in the next chapter.

A Preformed N-Linked Oligosaccharide Is Added to Many Proteins in the Rough ER

Biosynthesis of all N-linked oligosaccharides begins in the rough ER with addition of a preformed oligosaccharide precursor containing 14 residues (Figure 13-17). The structure of this precursor is the same in plants, animals, and single-celled eukaryotes: a branched oligosaccharide, containing three glucose (Glc), nine mannose (Man), and two N-acetylglucosamine (GlcNAc) molecules, which can be written as $\text{Glc}_3\text{Man}_9(\text{GlcNAc})_2$. Once added to a protein, this branched carbohydrate structure is modified by addition or removal of monosaccharides in the ER and Golgi compartments. The modifications to N-linked chains differ from one glycoprotein to another and differ among different organisms, but a core of 5 of the 14 residues is conserved in the structures of all N-linked oligosaccharides on secretory and membrane proteins.

Prior to transfer to a nascent chain in the lumen of the ER, the precursor oligosaccharide is assembled on a membrane-attached anchor called *dolichol phosphate*, a long-chain polyisoprenoid lipid (Chapter 10). After the first sugar, GlcNAc, is attached to the dolichol phosphate by a pyrophosphate bond, the other sugars are added by glycosidic bonds in a complex set of reactions catalyzed by enzymes attached to the cytosolic or luminal faces of the rough ER membrane (Figure 13-17). The final dolichol pyrophosphoryl

oligosaccharide is oriented so that the oligosaccharide portion faces the ER lumen.

The entire 14-residue precursor is transferred from the dolichol carrier to an asparagine residue on a nascent polypeptide as it emerges into the ER lumen (Figure 13-18, step 1). Only asparagine residues in the tripeptide sequences Asn-X-Ser and Asn-X-Thr (where X is any amino acid except proline) are substrates for *oligosaccharyl transferase*, the enzyme that catalyzes this reaction. Two of the three subunits of this enzyme are ER membrane proteins whose cytosol-facing domains bind to the ribosome, localizing a third subunit of the transferase, the catalytic subunit, near the growing polypeptide chain in the ER lumen. Not all Asn-X-Ser/Thr sequences become glycosylated, and it is not possible to predict from the amino acid sequence alone which potential N-linked glycosylation sites will be modified; for instance, rapid folding of a segment of a protein containing an Asn-X-Ser/Thr sequence may prevent transfer of the oligosaccharide precursor to it.

Immediately after the entire precursor, $\text{Glc}_3\text{Man}_9(\text{GlcNAc})_2$, is transferred to a nascent polypeptide, three different enzymes, called glycosidases, remove all three glucose residues and one particular mannose residue (Figure 13-18, steps 2–4). The three glucose residues, which are the last residues added during synthesis of the precursor on the dolichol carrier, appear to act as a signal that the oligosaccharide is complete and ready to be transferred to a protein.

FIGURE 13-17 Biosynthesis of the oligosaccharide precursor. Dolichol phosphate is a strongly hydrophobic lipid, containing 75–95 carbon atoms, that is embedded in the ER membrane. Two N-acetylglucosamine (GlcNAc) and five mannose residues are added one at a time to a dolichol phosphate on the cytosolic face of the ER membrane (steps 1–3). The nucleotide-sugar donors in these and later reactions are synthesized in the cytosol. Note that the first sugar residue is attached to dolichol by a high-energy pyrophosphate linkage. Tunicamycin, which blocks the first enzyme in this pathway, inhibits the synthesis of all N-linked oligosaccharides in cells. After the

seven-residue dolichol pyrophosphoryl intermediate is flipped to the luminal face (step 4), the remaining four mannose and all three glucose residues are added one at a time (steps 5, 6). In the later reactions, the sugar to be added is first transferred from a nucleotide-sugar to a carrier dolichol phosphate on the cytosolic face of the ER; the carrier is then flipped to the luminal face, where the sugar is transferred to the growing oligosaccharide, after which the “empty” carrier is flipped back to the cytosolic face. [After C. Abeijon and C. B. Hirschberg, 1992, *Trends Biochem. Sci.* 17:32.]

FIGURE 13-18 Addition and initial processing of *N*-linked oligosaccharides. In the rough ER of vertebrate cells, the $\text{Glc}_3\text{Man}_9(\text{GlcNAc})_2$ precursor is transferred from the dolichol carrier to a susceptible asparagine residue on a nascent protein as soon as the asparagine crosses to the luminal side of the ER (step **1**). In three separate reactions, first one glucose residue (step **2**), then two glucose residues (step **3**), and finally one mannose residue (step **4**) are

removed. Re-addition of one glucose residue (step **3a**) plays a role in the correct folding of many proteins in the ER, as discussed later. The process of *N*-linked glycosylation of a soluble secretory protein is shown here, but the luminal portions of an integral membrane protein can be modified on asparagine residues by the same mechanism. [See R. Kornfeld and S. Kornfeld, 1985, *Ann. Rev. Biochem.* **45**:631, and M. Sousa and A. J. Parodi, 1995, *EMBO J.* **14**:4196.]

Oligosaccharide Side Chains May Promote Folding and Stability of Glycoproteins

The oligosaccharides attached to glycoproteins serve various functions. For example, some proteins require *N*-linked oligosaccharides in order to fold properly in the ER. This function has been demonstrated in studies with the antibiotic tunicamycin, which blocks the first step in the formation of the dolichol-linked oligosaccharide precursor and therefore inhibits synthesis of all *N*-linked oligosaccharides in cells (see Figure 13-17, *top left*). For example, in the presence of tunicamycin, the flu virus hemagglutinin precursor polypeptide (HA_0) is synthesized, but it cannot fold properly and form a normal trimer; in this case, the protein remains, misfolded, in the rough ER. Moreover, mutation of a particular asparagine in the HA sequence to a glutamine residue prevents addition of an *N*-linked oligosaccharide to that site and causes the protein to accumulate in the ER in an unfolded state.

In addition to promoting proper folding, *N*-linked oligosaccharides also confer stability on many secreted glycoproteins. Many secretory proteins fold properly and are transported to their final destination even if the addition of all *N*-linked oligosaccharides is blocked, for example, by tunicamycin. However, such nonglycosylated proteins have been shown to be less stable than their glycosylated forms. For instance, glycosylated fibronectin, a normal component of the extracellular matrix, is degraded much more slowly by tissue proteases than is nonglycosylated fibronectin.

Oligosaccharides on certain cell-surface glycoproteins also play a role in cell-cell adhesion. For example, the plasma membrane of white blood cells (leukocytes) contains cell-adhesion molecules (CAMs) that are extensively glycosylated. The oligosaccharides in these molecules interact with a sugar-binding

domain in certain CAMs found on endothelial cells lining blood vessels. This interaction tethers the leukocytes to the endothelium and assists in their movement into tissues during an inflammatory response to infection (see Figure 20-39). Other cell-surface glycoproteins possess oligosaccharide side chains that can induce an immune response. A common example is the A, B, O blood-group antigens, which are O-linked oligosaccharides attached to glycoproteins and glycolipids on the surface of erythrocytes and other cell types (Figure 10-20). In both cases, oligosaccharides are added to the luminal face of these membrane proteins, in a manner similar to what is shown in Figure 13-18 for soluble proteins. The luminal face of these membrane proteins is topologically equivalent to the exterior face of the plasma membrane, where these proteins eventually end up.

Disulfide Bonds Are Formed and Rearranged by Proteins in the ER Lumen

In Chapter 3 we learned that both intramolecular and intermolecular **disulfide bonds** ($-\text{S}-\text{S}-$) help stabilize the tertiary and quaternary structure of many proteins. These covalent bonds form by the oxidative linkage of **sulfhydryl groups** ($-\text{SH}$), also known as *thiol* groups, on two cysteine residues in the same or different polypeptide chains. This reaction can proceed spontaneously only when a suitable oxidant is present. In eukaryotic cells, disulfide bonds are formed only in the lumen of the rough ER. Thus disulfide bonds are found only in soluble secretory proteins and in the exoplasmic domains of membrane proteins. Cytosolic proteins and organelle proteins synthesized on free ribosomes (i.e., those destined for mitochondria, chloroplasts, peroxisomes, etc.) usually lack disulfide bonds.

The efficient formation of disulfide bonds in the lumen of the ER depends on the enzyme *protein disulfide isomerase* (PDI), which is present in all eukaryotic cells. This enzyme is especially abundant in the ER of secretory cells in such organs as the liver and pancreas, where large quantities of proteins that contain disulfide bonds are produced. As shown in Figure 13-19a, the disulfide bond in the active site of PDI can be readily transferred to a protein by two sequential thiol-disulfide transfer reactions. The reduced PDI generated by this reaction is returned to an oxidized form by the action of an ER-resident protein, called *Ero1*, which carries a disulfide bond that can be transferred to PDI. *Ero1* itself becomes oxidized by reaction with molecular oxygen that has diffused into the ER.

In proteins that contain more than one disulfide bond, the proper pairing of cysteine residues is essential for normal structure and activity. Disulfide bonds commonly are formed between cysteines that occur sequentially in the amino acid

sequence while a polypeptide is still growing on the ribosome. Such sequential formation, however, sometimes yields disulfide bonds between the wrong cysteines. For example, proinsulin, a precursor to the peptide hormone insulin, has three disulfide bonds that link cysteines 1 and 4, 2 and 6, and 3 and 5. In this case, a disulfide bond that initially formed sequentially (e.g., between cysteines 1 and 2) would have to be rearranged for the protein to achieve its proper folded conformation. In cells, the rearrangement of disulfide bonds also is accelerated by PDI, which acts on a broad range of protein substrates, allowing them to reach their thermodynamically most stable conformations (Figure 13-19b). Disulfide bonds generally form in a specific order, first stabilizing small domains of a polypeptide, then stabilizing the interactions of more distant segments; this phenomenon is illustrated by the folding of influenza hemagglutinin (HA) protein, discussed in the next section.

FIGURE 13-19 Action of protein disulfide isomerase (PDI). PDI forms and rearranges disulfide bonds via an active site with two closely spaced cysteine residues that are easily interconverted between the reduced dithiol form and the oxidized disulfide form. Numbered red arrows indicate the sequence of electron transfers. Yellow bars represent disulfide bonds. (a) In the formation of disulfide bonds, the ionized ($-S^-$) form of a cysteine thiol in the substrate protein reacts with the disulfide ($S-S$) bond in oxidized PDI to form a disulfide-bonded PDI-substrate protein intermediate. A second ionized thiol in

the substrate then reacts with this intermediate, forming a disulfide bond within the substrate protein and releasing reduced PDI. PDI, in turn, transfers electrons to a disulfide bond in the luminal protein *Ero1*, thereby regenerating the oxidized form of PDI. (b) Reduced PDI can catalyze rearrangement of improperly formed disulfide bonds by similar thiol-disulfide transfer reactions. In this case, reduced PDI both initiates and is regenerated in the reaction pathway. These reactions are repeated until the most stable conformation of the protein is achieved. [See M. M. Lyles and H. F. Gilbert, 1991, *Biochemistry* 30:619.]

Chaperones and Other ER Proteins Facilitate Folding and Assembly of Proteins

Although many denatured proteins can spontaneously refold into their native state *in vitro*, such refolding usually requires hours to reach completion. Yet new soluble and membrane proteins produced in the ER generally fold into their proper conformation within minutes after their synthesis. The rapid folding of these newly synthesized proteins in cells depends on the sequential action of several proteins present within the ER lumen. We have already seen how the molecular chaperone BiP can drive post-translational translocation in yeast by binding fully synthesized polypeptides as they enter the ER (see Figure 13-9). BiP can also bind transiently to

nascent chains as they enter the ER during cotranslational translocation. Bound BiP is thought to prevent segments of a nascent chain from misfolding or forming aggregates, thereby promoting folding of the entire polypeptide into the proper conformation. Protein disulfide isomerase (PDI) also contributes to proper folding, because correct 3-D conformation is stabilized by disulfide bonds in many proteins.

As illustrated in Figure 13-20, two other ER proteins, the homologous lectins (carbohydrate-binding proteins) *calnexin* and *calreticulin*, bind selectively to certain *N*-linked oligosaccharides on growing nascent chains. The ligand for these two lectins, which resembles the *N*-linked oligosaccharide precursor but that has only a single glucose residue

FIGURE 13-20 Hemagglutinin folding and assembly.

(a) Mechanism of HA₀ trimer assembly. Transient binding of the chaperone BiP (step 1a) to the nascent chain and of two lectins, calnexin and calreticulin, to certain oligosaccharide chains (step 1b) promotes proper folding of adjacent segments. A total of seven *N*-linked oligosaccharide chains are added to the luminal portion of the nascent chain during cotranslational translocation, and PDI catalyzes the formation of six disulfide bonds per monomer. Completed HA₀ monomers are anchored in the membrane by a single membrane-spanning α helix with the N-terminus in the lumen (step 2). Interaction of three HA₀ chains with one another, initially via their transmembrane α helices, apparently triggers formation of a long stem containing one α helix from the luminal part of each HA₀ polypeptide. Finally, interactions occur among the three globular heads, generating a stable HA₀ trimer (step 3). (b) Electron micrograph of a complete influenza virion showing trimers of HA protein protruding as spikes from the surface of the viral membrane. [Part (a), see U. Tatu et al., 1995, *EMBO J.* **14**:1340, and D. Hebert et al., 1997, *J. Cell Biol.* **139**:613. Part (b), Chris Bjornberg/Photo Researchers, Inc.]

[Glc₁Man₉(GlcNAc)₂], is generated by a specific glucosyltransferase in the ER lumen (see Figure 13-18, step 3a). This enzyme acts only on polypeptide chains that are unfolded or misfolded, and in this respect the glucosyltransferase acts as one of the primary surveillance mechanisms to ensure quality control of protein folding in the ER, but the mechanism by which the glucosyltransferase distinguishes folded and unfolded proteins is not yet understood. Binding of calnexin and calreticulin to unfolded nascent chains marked with glucosylated *N*-linked oligosaccharides prevents aggregation of adjacent segments of a protein as it is being made on the ER. Thus calnexin and calreticulin, like BiP, help prevent premature, incorrect folding of segments of a newly made protein.

Other important protein-folding catalysts in the ER lumen are *peptidyl-prolyl isomerases*, a family of enzymes that accelerate the rotation about peptidyl-prolyl bonds at proline residues in unfolded segments of a polypeptide:

Such isomerizations sometimes are the rate-limiting step in the folding of protein domains. Many peptidyl-prolyl isomerases can catalyze the rotation of exposed peptidyl-prolyl bonds indiscriminately in numerous proteins, but some have very specific protein substrates.

Many important soluble secretory and membrane proteins synthesized on the ER are built of two or more polypeptide subunits. In all cases, the assembly of subunits constituting these multisubunit (multimeric) proteins occurs in the ER. An important class of multimeric secreted proteins is the immunoglobulins, which contain two heavy (H) and two light (L) chains, all linked by intrachain disulfide bonds. Hemagglutinin (HA) is another multimeric protein that provides a good illustration of folding and subunit assembly (see Figure 13-20). This trimeric protein forms the spikes that protrude from the surface of an influenza virus particle. The HA trimer is formed within the ER of an infected host cell from three copies of a precursor protein termed HA₀, which has a single membrane-spanning α helix. In the Golgi complex, each of the three HA₀ proteins is cleaved to form two polypeptides, HA₁ and HA₂; thus each HA molecule that eventually resides on the viral surface contains three copies of HA₁ and three of HA₂ (see Figure 3-10). The trimer is stabilized by interactions between the large exoplasmic domains of the constituent polypeptides, which extend into the ER lumen; after HA is transported to the cell surface, these domains extend into the extracellular space. Interactions between the smaller cytosolic

and membrane-spanning portions of the HA subunits also help stabilize the trimeric protein. Studies have shown that it takes just 10 minutes for the HA₀ polypeptides to fold and assemble into their proper trimeric conformation.

Improperly Folded Proteins in the ER Induce Expression of Protein-Folding Catalysts

Wild-type proteins that are synthesized on the rough ER cannot exit this compartment until they achieve their completely folded conformation. Likewise, almost any mutation that prevents proper folding of a protein in the ER also blocks movement of the polypeptide from the ER lumen or membrane to the Golgi complex. The mechanisms for retaining unfolded or incompletely folded proteins within the ER probably increase the overall efficiency of folding by keeping intermediate forms in proximity to folding catalysts, which are most abundant in the ER. Improperly folded proteins retained within the ER generally are seen bound to the ER chaperones BiP and calnexin. Thus these luminal folding catalysts perform two related functions: assisting in the folding of normal proteins by preventing their aggregation and binding to misfolded proteins to retain them in the ER.

Both mammalian cells and yeasts respond to the presence of unfolded proteins in the rough ER by increasing transcription of several genes encoding ER chaperones and other folding catalysts. A key participant in this *unfolded-protein response* is Ire1, an ER membrane protein that exists as both a monomer and a dimer. The dimeric form, but not the monomeric form, promotes formation of Hac1, a transcription factor in yeast that activates expression of the genes induced in the unfolded-protein response. As depicted in Figure 13-21, binding of BiP to the luminal domain of monomeric Ire1 prevents formation of the Ire1 dimer. Thus the quantity of free BiP in the ER lumen determines the relative proportion of monomeric and dimeric Ire1. Accumulation of unfolded proteins within the ER lumen sequesters BiP molecules, making them unavailable for binding to Ire1. As a result, the level of dimeric Ire1 increases, leading to an increase in the level of Hac1 and production of proteins that assist in protein folding.

Mammalian cells contain an additional regulatory pathway that operates in response to unfolded proteins in the ER. In this pathway, accumulation of unfolded proteins in the ER triggers proteolysis of ATF6, a transmembrane protein in the ER membrane, at a site within the membrane-spanning segment. The cytosolic domain of ATF6 released by proteolysis then moves to the nucleus, where it stimulates transcription of the genes encoding ER chaperones. Activation of a transcription factor by such *regulated intramembrane proteolysis* also occurs in the Notch signaling pathway and during activation of the cholesterol-responsive transcription factor SREBP (see Figures 16-35 and 16-37).

 A hereditary form of emphysema illustrates the detrimental effects that can result from misfolding of proteins in the ER. This disease is caused by a point mutation in α_1 -antitrypsin, which normally is secreted by hepatocytes and

FIGURE 13-21 The unfolded-protein response. Ire1, a transmembrane protein in the ER membrane, has a binding site for BiP on its luminal domain; the cytosolic domain contains a specific RNA endonuclease. **Step 1:** Accumulating unfolded proteins in the ER lumen bind BiP molecules, releasing them from monomeric Ire1. Dimerization of Ire1 then activates its endonuclease activity. **Steps 2, 3:** The unspliced mRNA precursor encoding the transcription factor Hac1 is cleaved by dimeric Ire1, and the two exons are joined to form functional Hac1 mRNA. Current evidence indicates that this processing occurs in the cytosol, although pre-mRNA processing generally occurs in the nucleus. **Step 4:** Hac1 is translated into Hac1 protein, which then moves back into the nucleus and activates transcription of genes encoding several protein-folding catalysts. [See U. Ruegsegger et al., 2001, *Cell* **107**:103; A. Bertolotti et al., 2000, *Nat. Cell Biol.* **2**:326; and C. Sidrauski and P. Walter, 1997, *Cell* **90**:1031.]

macrophages. The wild-type protein binds to and inhibits trypsin and also the blood protease elastase. In the absence of α_1 -antitrypsin, elastase degrades the fine tissue in the lung that participates in the absorption of oxygen, eventually producing the symptoms of emphysema. Although the mutant α_1 -antitrypsin is synthesized in the rough ER, it does not fold properly, forming an almost crystalline aggregate that is not exported from the ER. In hepatocytes, the secretion of other proteins also becomes impaired as the rough ER is filled with aggregated α_1 -antitrypsin. ■

Unassembled or Misfolded Proteins in the ER Are Often Transported to the Cytosol for Degradation

Misfolded soluble secretory and membrane proteins, as well as the unassembled subunits of multimeric proteins, often are degraded within an hour or two after their synthesis in the rough ER. For many years, researchers thought that proteolytic enzymes within the ER lumen catalyzed degradation of misfolded or unassembled polypeptides, but such proteases were never found. More recent studies have shown that misfolded secretory proteins are recognized by specific ER membrane proteins and are targeted for transport from the ER lumen into the cytosol, by a process known as *dislocation*.

The dislocation of misfolded proteins out of the ER depends on a set of proteins located in the ER membrane and in the cytosol that perform three basic functions. The first function is recognition of misfolded proteins that will be substrates for the dislocation reaction. One mechanism for recognition involves trimming of N-linked carbohydrate chains by the enzyme α -mannosidase I (Figure 13-22). Trimmed glycans of the structure $\text{Man}_8(\text{GlcNAc})_2$ are recognized by the lectinlike protein known as EDEM, and glycans that are further trimmed to $\text{Man}_7(\text{GlcNAc})_2$ are recognized by the lectinlike protein OS-9. Both EDEM and OS-9 target the trimmed glycoprotein to the dislocation complex for degradation. It is not known precisely how α -mannosidase I distinguishes proteins that cannot fold properly, and are thus legitimate substrates for the dislocation process, from normal

proteins that have transient partially folded states as they acquire their fully folded conformation. One possibility is that trimming of N-linked carbohydrate chains by the α -mannosidase I may occur slowly, such that only those glycoproteins that remain misfolded in the ER lumen for a sufficiently long time are trimmed and therefore targeted for degradation. Luminal proteins that lack carbohydrate chains altogether can also be targeted for degradation, indicating that other processes for the recognition of unfolded proteins must also exist. Other mechanisms to recognize unfolded proteins that do not involve trimming of N-linked carbohydrate chains must exist because misfolded membrane proteins that lack N-linked carbohydrate chains altogether can nevertheless be targeted for degradation.

Once an unfolded protein has been identified, it is targeted for dislocation across the ER membrane. Some kind of channel must exist for dislocation of misfolded proteins across the ER membrane, and a complex of at least four integral membrane proteins, known as the ERAD (*ER-associated degradation*) complex, appears to serve this function. The structure of the dislocation channel and the mechanism by which misfolded proteins traverse the ER membrane are not yet known.

As segments of the dislocated polypeptide are exposed to the cytosol, they encounter cytosolic enzymes that drive dislocation. One of these enzymes is an ATPase called p97, a member of a protein family known as the AAA ATPase family, which couple the energy of ATP hydrolysis to disassembly of protein complexes. In retrotranslocation, hydrolysis of ATP by p97 may provide the driving force to pull misfolded proteins from the ER membrane into the cytosol. As misfolded

FIGURE 13-22 Modifications of *N*-linked oligosaccharides are used to monitor folding and quality control. After removal of three glucose residues from the *N*-linked oligosaccharides in the ER, a single glucose can be re-added by a glucosyl transferase to form $\text{Glc}_1\text{Man}_9(\text{GlcNAc})_2$ (see Figure 13-18, step 8a). This modified *N*-linked carbohydrate binds the lectins calnexin (CNX) and calreticulin (CRT) for retention in the ER and engagement of folding chaperones. Proteins

that cannot fold and are therefore retained in the ER for longer times undergo mannose trimming by mannosidase I to form $\text{Man}_8(\text{GlcNAc})_2$, which is recognized by the lectin EDEM, or further trimming to $\text{Man}_{7.5}(\text{GlcNAc})_2$, which is recognized by OS-9. Recognition by either EDEM or OS-9 leads to dislocation of the misfolded protein out of the ER, ubiquitination, and degradation by the proteasome.

proteins reenter the cytosol, specific ubiquitin ligase enzymes in the ER membrane add ubiquitin residues to the dislocated peptide. Like the action of p97, the ubiquitination reaction is coupled to ATP hydrolysis; this release of energy possibly also contributes to trapping proteins in the cytosol. The resulting polyubiquitinated polypeptides, now fully in the cytosol, are removed from the cell altogether by degradation in the proteasome. The role of polyubiquitination in targeting proteins to the proteasome is discussed more fully in Chapter 3 (see Figure 3-29 and Figure 3-34).

KEY CONCEPTS of Section 13.3

Protein Modifications, Folding, and Quality Control in the ER

- All *N*-linked oligosaccharides, which are bound to asparagine residues, contain a core of two *N*-acetylglucosamine and at least three mannose residues and usually have several branches. *O*-linked oligosaccharides, which are bound to serine or threonine residues, are generally short, often containing only one to four sugar residues.
- Formation of *N*-linked oligosaccharides begins with assembly of a conserved 14-residue high-mannose precursor on dolichol, a lipid in the membrane of the rough ER (see Figure 13-17). After this preformed oligosaccharide is transferred to specific asparagine residues of nascent polypeptide chains in the ER lumen, three glucose residues and one mannose residue are removed (see Figure 13-18).
- Oligosaccharide side chains may assist in the proper folding of glycoproteins, help protect the mature proteins from proteolysis, participate in cell-cell adhesion, and function as antigens.

- Disulfide bonds are added to many soluble secretory proteins and the exoplasmic domain of membrane proteins in the ER. Protein disulfide isomerase (PDI), present in the ER lumen, catalyzes both the formation and the rearrangement of disulfide bonds (see Figure 13-19).
- The chaperone BiP, the lectins calnexin and calreticulin, and peptidyl-prolyl isomerases work together to ensure proper folding of newly made secretory and membrane proteins in the ER. The subunits of multimeric proteins also assemble in the ER (see Figure 13-20).
- Only properly folded proteins and assembled subunits are transported from the rough ER to the Golgi complex in vesicles.
- The accumulation of abnormally folded proteins and unassembled subunits in the ER can induce increased expression of ER protein-folding catalysts via the unfolded-protein response (see Figure 13-21).
- Unassembled or misfolded proteins in the ER often are transported back to the cytosol, where they are degraded in the ubiquitin/proteasome pathway (see Figure 13-22).

13.4 Targeting of Proteins to Mitochondria and Chloroplasts

In the remainder of this chapter, we examine how proteins synthesized on cytosolic ribosomes are sorted to mitochondria, chloroplasts, peroxisomes, and the nucleus (see Figure 13-1). In both mitochondria and chloroplasts, an internal lumen called the *matrix* is surrounded by a double membrane, and internal subcompartments exist within the matrix. In contrast,

peroxisomes are bounded by a single membrane and have a single luminal matrix compartment. Because of these and other differences, we consider peroxisomes separately in the next section. The mechanism of protein transport into and out of the nucleus differs in many respects from sorting to other organelles; this is discussed in the last section.

In addition to being bounded by two membranes, mitochondria and chloroplasts share similar types of electron-transport proteins and use an F-class ATPase to synthesize ATP (see Figure 12-24). Remarkably, these characteristics are shared by gram-negative bacteria. Also like bacterial cells, mitochondria and chloroplasts contain their own DNA, which encodes organelle rRNAs, tRNAs, and some proteins (Chapter 6). Moreover, growth and division of mitochondria and chloroplasts are not coupled to nuclear division. Rather, these organelles grow by the incorporation of cellular proteins and lipids, and new organelles form by division of preexisting organelles. The numerous similarities of free-living bacterial cells with mitochondria and chloroplasts have led to the understanding that these organelles arose by the incorporation of bacteria into ancestral eukaryotic cells, forming endosymbiotic organelles (see Figure 6-20). The sequence similarity of many membrane translocation proteins shared by mitochondria, chloroplasts, and bacteria provides the most striking evidence for this ancient evolutionary relationship. In this section we will examine these membrane translocation proteins in detail.

Proteins encoded by mitochondrial DNA or chloroplast DNA are synthesized on ribosomes within the organelles and directed to the correct subcompartment immediately after synthesis. The majority of proteins located in mitochondria and chloroplasts, however, are encoded by genes in the nucleus and are imported into the organelles after their synthesis in the cytosol. Apparently, as eukaryotic cells evolved over a billion years, much of the genetic information from the ancestral bacterial DNA in these endosymbiotic organelles moved, by an unknown mechanism, to the nucleus. Precursor proteins synthesized in the cytosol that are destined for the matrix of mitochondria or the equivalent space in chloroplasts, the stroma, usually contain specific N-terminal uptake-targeting sequences that specify binding to receptor proteins on the organelle surface. Generally, this sequence is cleaved once it reaches the matrix or stroma. Clearly, these uptake-targeting sequences are similar in their location and general function to the signal sequences that direct nascent proteins to the ER lumen. Although the three types of signals share some common sequence features, their specific sequences differ considerably, as summarized in Table 13-1.

In both mitochondria and chloroplasts, protein import requires energy and occurs at points where the outer and inner organelle membranes are in close contact. Because mitochondria and chloroplasts contain multiple membranes and membrane-limited spaces, sorting of many proteins to their correct location often requires the sequential action of

TABLE 13-1 Uptake-Targeting Sequences That Direct Proteins from the Cytosol to Organelles*

Target Organelle	Location of Sequence Within Protein	Removal of Sequence	Nature of Sequence
Endoplasmic reticulum (lumen)	N-terminus	Yes	Core of 6–12 hydrophobic amino acids, often preceded by one or more basic amino acids (Arg, Lys)
Mitochondrion (matrix)	N-terminus	Yes	Amphipathic helix, 20–50 residues in length, with Arg and Lys residues on one side and hydrophobic residues on the other
Chloroplast (stroma)	N-terminus	Yes	No common motifs; generally rich in Ser, Thr, and small hydrophobic residues and poor in Glu and Asp
Peroxisome (matrix)	C-terminus (most proteins); N-terminus (few proteins)	No	PTS1 signal (Ser-Lys-Leu) at extreme C-terminus; PTS2 signal at N-terminus
Nucleus (nucleoplasm)	Varies	No	Multiple different kinds; a common motif includes a short segment rich in Lys and Arg residues

*Different or additional sequences target proteins to organelle membranes and subcompartments.

EXPERIMENTAL FIGURE 13-23 Import of mitochondrial precursor proteins is assayed in a cell-free system. Mitochondrial precursor proteins with attached uptake-targeting signals can be synthesized on ribosomes in a cell-free reaction. When respiring mitochondria are added to the synthesized mitochondrial precursor proteins (top), the proteins are taken up by mitochondria. Inside mitochondria, proteins are protected from the action of proteases such as trypsin. When no mitochondria are present (bottom), mitochondrial proteins are degraded by added protease. Protein uptake occurs only with energized (respiring) mitochondria, which have a proton electrochemical gradient (proton-motive force) across the inner membrane. The imported protein must contain an appropriate uptake-targeting sequence. Uptake also requires ATP and a cytosolic extract containing chaperone proteins that maintain the precursor proteins in an unfolded conformation. This assay has been used to study targeting sequences and other features of the translocation process.

two targeting sequences and two membrane-bound translocation systems: one to direct the protein into the organelle and the other to direct it into the correct organellar compartment or membrane. As we will see, the mechanisms for sorting various proteins to mitochondria and chloroplasts are related to some of the mechanisms discussed previously.

Amphipathic N-Terminal Signal Sequences Direct Proteins to the Mitochondrial Matrix

All proteins that travel from the cytosol to the same mitochondrial destination have targeting signals that share common motifs, although the signal sequences are generally not identical. Thus the receptors that recognize such signals are able to bind to a number of different but related sequences. The most extensively studied sequences for localizing proteins to mitochondria are the *matrix-targeting sequences*. These sequences, located at the N-terminus, are usually 20–50 amino acids in length. They are rich in hydrophobic amino acids, positively charged basic amino acids (arginine and lysine), and hydroxylated ones (serine and threonine) but tend to lack negatively charged acidic residues (aspartate and glutamate).

Mitochondrial matrix-targeting sequences are thought to assume an α -helical conformation in which positively charged amino acids predominate on one side of the helix and hydrophobic amino acids predominate on the other side. Sequences such as these that contain both hydrophobic and hydrophilic regions are said to be **amphipathic**. Mutations that disrupt this amphipathic character usually disrupt targeting to the matrix, although many other amino acid substitutions do not. These findings indicate that the amphipathicity of matrix-targeting sequences is critical to their function.

The cell-free assay outlined in Figure 13-23 has been widely used in studies to define the biochemical steps in the import of mitochondrial precursor proteins. In this system, respiring (energized) mitochondria extracted from cells can incorporate mitochondrial precursor proteins carrying appropriate uptake-targeting sequences that have been synthesized in the absence of mitochondria. Successful incorporation of the precursor into the organelle can be assayed either by resistance to digestion by an added protease such as trypsin. In other assays, successful import of a precursor protein can be shown by the proper cleavage of the N-terminal targeting sequences by specific mitochondrial proteases. The uptake of completely presynthesized mitochondrial precursor proteins by the organelle in this system contrasts with the cell-free co-translational translocation of secretory proteins into the ER, which generally occurs only when microsomal (ER-derived) membranes are present during synthesis (see Figure 13-4).

Mitochondrial Protein Import Requires Outer-Membrane Receptors and Translocons in Both Membranes

Figure 13-24 presents an overview of protein import from the cytosol into the mitochondrial matrix, the route into the mitochondrion followed by most imported proteins. We will discuss in detail each step of protein transport into the matrix and then consider how some proteins subsequently are targeted to other compartments of the mitochondrion.

After synthesis in the cytosol, the soluble precursors of mitochondrial proteins (including hydrophobic integral membrane proteins) interact directly with the mitochondrial membrane. In general, only unfolded proteins can be imported into

FIGURE 13-24 Protein import into the

mitochondrial matrix. Precursor proteins synthesized on cytosolic ribosomes are maintained in an unfolded or partially folded state by bound chaperones, such as Hsc70 (step 1). After a precursor protein binds to an import receptor near a site of contact with the inner membrane (step 2), it is transferred into the general import pore (step 3). The translocating protein then moves through this channel and an adjacent channel in the inner membrane (steps 4, 5). Note that translocation occurs at rare "contact sites" at which the inner and outer membranes appear to touch. Binding of the translocating protein by the matrix chaperone Hsc70 and subsequent ATP hydrolysis by Hsc70 helps drive import into the matrix. Once the uptake-targeting sequence is removed by a matrix protease and Hsc70 is released from the newly imported protein (step 6), it folds into the mature, active conformation within the matrix (step 7). Folding of some proteins depends on matrix chaperonins. [See G. Schatz, 1996, *J. Biol. Chem.* 271:31763, and N. Pfanner et al., 1997, *Ann. Rev. Cell Devel. Biol.* 13:25.]

the mitochondrion. Chaperone proteins such as cytosolic Hsc70 keep nascent and newly made proteins in an unfolded state so that they can be taken up by mitochondria. This process requires ATP hydrolysis. Import of an unfolded mitochondrial precursor is initiated by the binding of a mitochondrial targeting sequence to an *import receptor* in the outer mitochondrial membrane. These receptors were first identified by experiments in which antibodies to specific proteins of the outer mitochondrial membrane were shown to inhibit protein import into isolated mitochondria. Subsequent genetic experiments, in which the genes for specific mitochondrial outer-membrane proteins were mutated, showed that specific receptor proteins were responsible for the import of different classes of mitochondrial proteins. For example, N-terminal matrix-targeting sequences are recognized by Tom20 and Tom22. (Proteins in the outer mitochondrial membrane

involved in targeting and import are designated *Tom* proteins, for translocon of the outer membrane.)

The import receptors subsequently transfer the precursor proteins to an import channel in the outer membrane. This channel, composed mainly of the Tom40 protein, is known as the *general import pore* because all known mitochondrial precursor proteins gain access to the interior compartments of the mitochondrion through this channel. When Tom40 is purified and incorporated into liposomes, it forms a transmembrane channel with a pore wide enough to accommodate an unfolded polypeptide chain. The general import pore forms a largely passive channel through the outer mitochondrial membrane, and the driving force for unidirectional transport into mitochondria comes from within the mitochondrion. In the case of precursors destined for the mitochondrial matrix, transfer through the outer membrane

occurs simultaneously with transfer through an inner-membrane channel composed of the Tim23 and Tim17 proteins. (*Tim* stands for *translocon of the inner membrane*.) Translocation into the matrix thus occurs at “contact sites” where the outer and inner membranes are in close proximity.

Soon after the N-terminal matrix-targeting sequence of a protein enters the mitochondrial matrix, it is removed by a protease that resides within the matrix. The emerging protein also is bound by matrix Hsc70, a chaperone that is localized to the translocation channels in the inner mitochondrial membrane by interacting with transmembrane protein Tim44. This interaction stimulates ATP hydrolysis by matrix Hsc70, and together these two proteins are thought to power translocation of proteins into the matrix.

Some imported proteins can fold into their final, active conformation without further assistance. Final folding of many matrix proteins, however, requires a **chaperonin**. As discussed in Chapter 3, chaperonin proteins actively facilitate protein folding in a process that depends on ATP. For instance, yeast mutants defective in Hsc60, a chaperonin in the mitochondrial matrix, can import matrix proteins and

cleave their uptake-targeting sequence normally, but the imported polypeptides fail to fold and assemble into the native tertiary and quaternary structures.

Studies with Chimeric Proteins Demonstrate Important Features of Mitochondrial Import

Dramatic evidence for the ability of mitochondrial matrix-targeting sequences to direct import was obtained with chimeric proteins produced by recombinant DNA techniques. For example, the matrix-targeting sequence of alcohol dehydrogenase can be fused to the N-terminus of dihydrofolate reductase (DHFR), which normally resides in the cytosol. In the presence of chaperones, which prevent the C-terminal DHFR segment from folding in the cytosol, cell-free translocation assays show that the chimeric protein is transported into the matrix (Figure 13-25a). The inhibitor methotrexate, which binds tightly to the active site of DHFR and greatly stabilizes its folded conformation, renders the chimeric protein resistant to unfolding by cytosolic chaperones. When translocation assays are performed in the presence of methotrexate, the chimeric protein

EXPERIMENTAL FIGURE 13-25 Experiments with chimeric proteins elucidate mitochondrial protein import. These experiments show that a matrix-targeting sequence alone directs proteins to the mitochondrial matrix and that only unfolded proteins are translocated across both membranes. The chimeric protein in these experiments contained a matrix-targeting signal at its N-terminus (red), followed by a spacer sequence of no particular function (black) and then by dihydrofolate reductase (DHFR), an enzyme normally present only in the cytosol. (a) When the DHFR segment is unfolded, the chimeric protein moves across both membranes to the matrix of energized mitochondria and the matrix-targeting signal is then removed. (b) When the C-terminus of the chimeric protein is locked in the folded state by binding of methotrexate, translocation is blocked. If

the spacer sequence is long enough to extend across both transport channels, a stable translocation intermediate, with the targeting sequence cleaved off, is generated in the presence of methotrexate, as shown here. (c) The C-terminus of the translocation intermediate in (b) can be detected by incubating the mitochondria with antibodies that bind to the DHFR segment, followed by gold particles coated with bacterial protein A, which binds nonspecifically to antibody molecules (see Figure 9-29). An electron micrograph of a sectioned sample reveals gold particles (red arrowhead) bound to the translocation intermediate at a contact site between the inner and outer membranes. Other contact sites (black arrows) also are evident. [Parts (a) and (b) adapted from J. Rassow et al., 1990, *FEBS Lett.* **275**:190. Part (c) from M. Schweiger et al., 1987, *J. Cell Biol.* **105**:235, courtesy of W. Neupert.]

does not completely enter the matrix. This finding demonstrates that a precursor must be unfolded in order to traverse the import pores in the mitochondrial membranes.

Additional studies revealed that if a sufficiently long spacer sequence separates the N-terminal matrix-targeting sequence and DHFR portion of the chimeric protein, then, in the presence of methotrexate, a translocation intermediate that spans both membranes can be trapped if enough of the polypeptide protrudes into the matrix to prevent the polypeptide chain from sliding back into the cytosol, possibly by stably associating with matrix Hsc70 (Figure 13-25b). In order for such a stable translocation intermediate to form, the spacer sequence must be long enough to span both membranes; a spacer of 50 amino acids extended to its maximum possible length is adequate to do so. If the chimera contains a shorter spacer—say, 35 amino acids—no stable translocation intermediate is obtained because the spacer cannot span both membranes. These observations provide further evidence that translocated proteins can span both inner and outer mitochondrial membranes and traverse these membranes in an unfolded state.

Microscopy studies of stable translocation intermediates show that they accumulate at sites where the inner and outer mitochondrial membranes are close together, evidence that precursor proteins enter only at such sites (Figure 13-25c). The distance from the cytosolic face of the outer membrane to the matrix face of the inner membrane at these *contact sites* is consistent with the length of an unfolded spacer sequence required for formation of a stable translocation intermediate. Moreover, stable translocation intermediates can be chemically cross-linked to the protein subunits that comprise the translocation channels of both the outer and inner membranes. This finding demonstrates that imported proteins can simultaneously engage channels in both the outer and inner mitochondrial membrane, as depicted in Figure 13-24. Since roughly 1000 stuck chimeric proteins can be observed in a typical yeast mitochondrion, it is thought that mitochondria have approximately 1000 general import pores for the uptake of mitochondrial proteins.

Three Energy Inputs Are Needed to Import Proteins into Mitochondria

As noted previously and indicated in Figure 13-24, ATP hydrolysis by Hsc70 chaperone proteins in both the cytosol and the mitochondrial matrix is required for import of mitochondrial proteins. Cytosolic Hsc70 expends energy to maintain bound precursor proteins in an unfolded state that is competent for translocation into the matrix. The importance of ATP to this function was demonstrated in studies in which a mitochondrial precursor protein was purified and then denatured (unfolded) by urea. When tested in the cell-free mitochondrial translocation system, the denatured protein was incorporated into the matrix in the absence of ATP. In contrast, import of the native, undenatured precursor required ATP for the normal unfolding function of cytosolic chaperones.

The sequential binding and ATP-driven release of multiple matrix Hsc70 molecules to a translocating protein may simply trap the unfolded protein in the matrix. Alternatively, the matrix Hsc70, anchored to the membrane by the Tim44 protein, may act as a molecular motor to pull the protein into the matrix (see Figure 13-24). In this case, the functions of matrix Hsc70 and Tim44 would be analogous to those of the chaperone BiP and Sec63 complex, respectively, in post-translational translocation into the ER lumen (see Figure 13-9).

The third energy input required for mitochondrial protein import is a H^+ electrochemical gradient, or *proton-motive force*, across the inner membrane. Recall from Chapter 12 that protons are pumped from the matrix into the intermembrane space during electron transport, creating a transmembrane potential across the inner membrane. In general, only mitochondria that are actively undergoing respiration, and therefore have generated a proton-motive force across the inner membrane, are able to translocate precursor proteins from the cytosol into the mitochondrial matrix. Treatment of mitochondria with inhibitors or uncouplers of oxidative phosphorylation, such as cyanide or dinitrophenol, dissipates this proton-motive force. Although precursor proteins still can bind tightly to receptors on such poisoned mitochondria, the proteins cannot be imported, either in intact cells or in cell-free systems, even in the presence of ATP and chaperone proteins. Scientists do not fully understand how the proton-motive force is used to facilitate entry of a precursor protein into the matrix. Once a protein is partially inserted into the inner membrane, it is subjected to a transmembrane potential of 200 mV (matrix space negative). This seemingly small potential difference is established across the very narrow hydrophobic core of the lipid bilayer, which gives an enormous electric gradient, equivalent to about 400,000 V/cm. One hypothesis is that the positive charges in the amphipathic matrix-targeting sequence could simply be “electrophoresed,” or pulled, into the matrix space by the inside-negative membrane electric potential.

Multiple Signals and Pathways Target Proteins to Submitochondrial Compartments

Unlike targeting to the matrix, targeting of proteins to the intermembrane space, inner membrane, and outer membrane of mitochondria generally requires more than one targeting sequence and occurs via one of several pathways. Figure 13-26 summarizes the organization of targeting sequences in proteins sorted to different mitochondrial locations.

Inner-Membrane Proteins Three separate pathways are known to target proteins to the inner mitochondrial membrane. One pathway makes use of the same machinery that is used for targeting of matrix proteins (Figure 13-27, path A). A cytochrome oxidase subunit called CoxVa is a protein transported by this pathway. The precursor form of CoxVa, which contains an N-terminal matrix-targeting sequence recognized by the Tom20/22 import receptor, is transferred through the Tom40 general import pore of the outer membrane and the

FIGURE 13-26 Targeting sequences in imported mitochondrial proteins. Most mitochondrial proteins have an N-terminal matrix-targeting sequence (pink) that is similar but not identical in different proteins. Proteins destined for the inner membrane, the intermembrane space, or the outer membrane have one or more additional targeting sequences that function to direct the proteins to these locations by several different pathways. The lettered pathways correspond to those illustrated in Figures 13-26 and 13-27. [See W. Neupert, 1997, *Ann. Rev. Biochem.* **66**:863.]

inner-membrane Tim23/17 translocation complex. In addition to the matrix-targeting sequence, which is cleaved during import, CoxVa contains a hydrophobic stop-transfer sequence. As the protein passes through the Tim23/17 channel, the stop-transfer sequence blocks translocation of the C-terminus across the inner membrane. The membrane-anchored intermediate is then transferred laterally into the bilayer of the inner membrane much as type I integral membrane proteins are incorporated into the ER membrane (see Figure 13-11).

A second pathway to the inner membrane is followed by proteins (e.g., ATP synthase subunit 9) whose precursors contain both a matrix-targeting sequence and internal hydrophobic

domains recognized by an inner-membrane protein termed *Oxa1*. This pathway is thought to involve translocation of at least a portion of the precursor into the matrix via the Tom40 and Tim23/17 channels. After cleavage of the matrix-targeting sequence, the protein is inserted into the inner membrane by a process that requires interaction with *Oxa1* and perhaps other inner-membrane proteins (Figure 13-27, path B). *Oxa1* is related to a bacterial protein involved in inserting some cytoplasmic membrane proteins in bacteria. This relatedness suggests that *Oxa1* may have descended from the translocation machinery in the endosymbiotic bacterium that eventually became the mitochondrion. However, the proteins forming the inner-membrane channels in mitochondria are not related to the

FIGURE 13-27 Three pathways to the inner mitochondrial membrane from the cytosol. Proteins with different targeting sequences are directed to the inner membrane via different pathways. In all three pathways, proteins cross the outer membrane via the Tom40 general import pore. Proteins delivered by pathways A and B contain an N-terminal matrix-targeting sequence that is recognized by the Tom20/22 import receptor in the outer membrane. Although both these pathways use the Tim23/17 inner-membrane channel, they differ in that the entire precursor protein enters the matrix and then is

redirected to the inner membrane in pathway B. Matrix Hsc70 plays a role similar to its role in the import of soluble matrix proteins (see Figure 13-23). Proteins delivered by pathway C contain internal sequences that are recognized by the Tom70/Tom22 import receptor; a different inner-membrane translocation channel (Tim22/54) is used in this pathway. Two intermembrane proteins (Tim9 and Tim10) facilitate transfer between the outer and inner channels. See the text for discussion. [See R. E. Dalbey and A. Kuhn, 2000, *Ann. Rev. Cell Dev. Biol.* **16**:51, and N. Pfanner and A. Geissler, 2001, *Nature. Rev. Mol. Cell Biol.* **2**:339.]

proteins in bacterial translocons. Oxa1 also participates in the inner-membrane insertion of certain proteins (e.g., subunit II of cytochrome oxidase) that are encoded by mitochondrial DNA and synthesized in the matrix by mitochondrial ribosomes.

The final pathway for insertion in the inner mitochondrial membrane is followed by multipass proteins that contain six membrane-spanning domains, such as the ADP/ATP antiporter. These proteins, which lack the usual N-terminal matrix-targeting sequence, contain multiple internal mitochondrial targeting sequences. After the internal sequences are recognized by a second import receptor composed of

outer-membrane proteins Tom70 and Tom22, the imported protein passes through the outer membrane via the general import pore (Figure 13-27, path C). The protein then is transferred to a second translocation complex in the inner membrane composed of the Tim22, Tim18, and Tim54 proteins. Transfer to the Tim22/18/54 complex depends on a multimeric complex of two small proteins, Tim9 and Tim10, which reside in the intermembrane space. The small Tim proteins are thought to act as chaperones, guiding imported protein precursors from the general import pore to the Tim22/18/54 complex in the inner membrane by binding to

their hydrophobic regions, preventing them from forming insoluble aggregates in the aqueous environment of the intermembrane space. Ultimately the Tim22/18/54 complex is responsible for incorporating the multiple hydrophobic segments of the imported protein into the inner membrane.

Intermembrane-Space Proteins Two pathways deliver cytosolic proteins to the space between the inner and outer mitochondrial membranes. The major pathway is followed by proteins, such as cytochrome b_2 , whose precursors carry two different N-terminal targeting sequences, both of which ultimately are cleaved. The most N-terminal of the two sequences is a matrix-targeting sequence, which is removed by the matrix protease. The second targeting sequence is a hydrophobic segment that blocks complete translocation of the protein across the inner membrane (Figure 13-28, path A). After the resulting membrane-embedded intermediate diffuses laterally away from the Tim23/17 translocation channel, a protease in the membrane cleaves the protein near the hydrophobic transmembrane segment, releasing the mature protein in a soluble form into the intermembrane space. Except for the second

proteolytic cleavage, this pathway is similar to that of inner-membrane proteins such as CoxVa (see Figure 13-27, path A).

The small Tim9 and Tim10 proteins, which reside in the intermembrane space, illustrate a second pathway for targeting to the intermembrane space. In this pathway, the imported proteins do not contain an N-terminal matrix-targeting sequence and are delivered directly to the intermembrane space via the general import pore without involvement of any inner-membrane translocation factors (Figure 13-28, path B). Translocation through the Tom40 general import pore does not seem to be coupled to any energetically favorable process; however, once located in the intermembrane space, Tim9 and Tim10 proteins acquire two disulfide bonds each and acquire compact stable folded structures. Apparently, the mechanism that drives unidirectional translocation through the outer membrane involves passive diffusion through the outer membrane, followed by folding and disulfide bond formation which irreversibly traps the protein in the intermembrane space. In many respects the process of disulfide bond formation in the intermembrane space resembles that of the ER lumen and involves a disulfide bond-generating protein Erv1 and a disulfide transfer protein Mia40.

FIGURE 13-28 Two pathways to the mitochondrial intermembrane space. Pathway A, the major one for delivery of proteins from the cytosol to the intermembrane space, is similar to pathway A for delivery to the inner membrane (see Figure 13-26). The major difference is that the internal targeting sequence in proteins such as cytochrome b_2 destined for the intermembrane space is recognized by an inner-membrane protease, which cleaves the protein on the intermembrane-space side of the membrane. The released protein then folds and binds to its heme cofactor within the intermembrane

space. Pathway B is a specialized pathway for delivery to the intermembrane space of the proteins Tim9 and Tim10. These proteins readily pass through the Tom40 general import pore and, once they are in the intermembrane space, fold and form disulfide bonds that prevent reverse translocation through Tom40. The disulfide bonds are generated by Erv1 and are transferred to Tim9 and Tim10 by Mia40. [See R. E. Dalbey and A. Kuhn, 2000, *Ann. Rev. Cell Dev. Biol.* **16**:51; N. Pfanner and A. Geissler, 2001, *Nat. Rev. Mol. Cell Biol.* **2**:339, and K. Tokatlidis, 2005, A disulfide relay system in mitochondria. *Cell* **121**:965–967.]

Outer-Membrane Proteins Many of the proteins that reside in the mitochondrial outer membrane, including the Tom40 pore itself and mitochondrial porin, have a β -barrel structure in which antiparallel strands form hydrophobic transmembrane segments surrounding a central channel. Such proteins are incorporated into the outer membrane by first interacting with the general import pore, Tom40, and then they are transferred to a complex known as the SAM (sorting and assembly machinery) complex, which is composed of at least three outer-membrane proteins. Presumably it is the very stable hydrophobic nature of β -barrel proteins that ultimately causes them to be stably incorporated into the outer membrane, but precisely how the SAM complex facilitates this process is not known.

Targeting of Chloroplast Stromal Proteins Is Similar to Import of Mitochondrial Matrix Proteins

Among the proteins found in the chloroplast stroma are the enzymes of the Calvin cycle, which functions in fixing carbon dioxide into carbohydrates during photosynthesis (Chapter 12). The large (L) subunit of ribulose 1,5-bisphosphate carboxylase (rubisco) is encoded by chloroplast DNA and synthesized on chloroplast ribosomes in the stromal space. The small (S) subunit of rubisco and all the other Calvin-cycle enzymes are encoded by nuclear genes and transported to chloroplasts after their synthesis in the cytosol. The precursor forms of these stromal proteins contain an N-terminal *stromal-import* sequence (see Table 13-1).

Experiments with isolated chloroplasts, similar to those with mitochondria illustrated in Figure 13-23, have shown that they can import the S-subunit precursor after its synthesis. After the unfolded precursor enters the stromal space, it binds transiently to a stromal Hsc70 chaperone and the N-terminal sequence is cleaved. In reactions facilitated by Hsc60 chaperonins that reside within the stromal space, eight S subunits combine with the eight L subunits to yield the active rubisco enzyme.

The general process of stromal import appears to be very similar to that for importing proteins into the mitochondrial matrix (see Figure 13-24). At least three chloroplast outer-membrane proteins, including a receptor that binds the stromal-import sequence and a translocation channel protein, and five inner-membrane proteins are known to be essential for directing proteins to the stroma. Although these proteins are functionally analogous to the receptor and channel proteins in the mitochondrial membrane, they are not structurally homologous. The lack of sequence similarity between these chloroplast and mitochondrial proteins suggests that they may have arisen independently during evolution.

The available evidence suggests that chloroplast stromal proteins, like mitochondrial matrix proteins, are imported in the unfolded state. Import into the stroma depends on ATP hydrolysis catalyzed by a stromal Hsc70 chaperone whose function is similar to that of Hsc70 in the mitochondrial

matrix and BiP in the ER lumen. Unlike mitochondria, chloroplasts do not generate an electrochemical gradient (proton-motive force) across their inner membrane. Thus protein import into the chloroplast stroma appears to be powered solely by ATP hydrolysis.

Proteins Are Targeted to Thylakoids by Mechanisms Related to Translocation Across the Bacterial Cytoplasmic Membrane

In addition to the double membrane that surrounds them, chloroplasts contain a series of internal interconnected membranous sacs, the **thylakoids** (see Figure 12-31). Proteins localized to the thylakoid membrane or lumen carry out photosynthesis. Many of these proteins are synthesized in the cytosol as precursors containing multiple targeting sequences. For example, plastocyanin and other proteins destined for the thylakoid lumen require the successive action of two uptake-targeting sequences. The first is an N-terminal stromal-import sequence that directs the protein to the stroma by the same pathway that imports the rubisco S subunit. The second sequence targets the protein from the stroma to the thylakoid lumen. The role of these targeting sequences has been shown in experiments measuring the uptake of mutant proteins generated by recombinant DNA techniques into isolated chloroplasts. For instance, mutant plastocyanin that lacks the thylakoid-targeting sequence but contains an intact stromal-import sequence accumulates in the stroma and is not transported into the thylakoid lumen.

Four separate pathways for transporting proteins from the stroma into the thylakoid have been identified. All four pathways have been found to be closely related to analogous transport mechanisms in bacteria, illustrating the close evolutionary relationship between the stromal membrane and the bacterial cytoplasmic membrane. Transport of plastocyanin and related proteins into the thylakoid lumen from the stroma occurs by a chloroplast SRP-dependent pathway that utilizes a translocon similar to SecY, the bacterial version of the Sec61 complex (Figure 13-29, *left*). A second pathway for transporting proteins into the thylakoid lumen involves a protein related to bacterial protein SecA, which uses the energy from ATP hydrolysis to drive protein translocation through the SecY translocon. A third pathway, which targets proteins to the thylakoid membrane, depends on a protein related to the mitochondrial Oxa1 protein and the homologous bacterial protein (see Figure 13-27, path B). Some proteins encoded by chloroplast DNA and synthesized in the stroma or transported into the stroma from the cytosol are inserted into the thylakoid membrane via this pathway.

Finally, thylakoid proteins that bind metal-containing cofactors follow another pathway into the thylakoid lumen (Figure 13-29, *right*). The unfolded precursors of these proteins are first targeted to the stroma, where the N-terminal stromal-import sequence is cleaved off and the protein then folds and binds its cofactor. A set of thylakoid-membrane proteins assists in translocating the folded protein and bound

FIGURE 13-29 Transporting proteins to chloroplast thylakoids.

Two of the four pathways for transporting proteins from the cytosol to the thylakoid lumen are shown here. In these pathways, unfolded precursors are delivered to the stroma via the same outer-membrane proteins that import stromal-localized proteins. Cleavage of the N-terminal stromal-import sequence by a stromal protease then reveals the thylakoid-targeting sequence (step 1). At this point the two pathways diverge. In the SRP-dependent pathway (left), plastocyanin and similar proteins are kept unfolded in the stromal space by a set of chaperones (not shown) and, directed by the thylakoid-targeting sequence, bind to proteins that are closely related to the bacterial SRP, SRP receptor, and SecY translocon, which mediate movement into the lumen (step 2). After the thylakoid-targeting sequence is removed in

the thylakoid lumen by a separate endoprotease, the protein folds into its mature conformation (step 3). In the pH-dependent pathway (right), metal-binding proteins fold in the stroma, and complex redox cofactors are added (step 2). Two arginine residues (RR) at the N-terminus of the thylakoid-targeting sequence and a pH gradient across the inner membrane are required for transport of the folded protein into the thylakoid lumen (step 2). The translocon in the thylakoid membrane is composed of at least four proteins related to proteins in the bacterial cytoplasmic membrane. The thylakoid targeting sequence containing the two arginine residues is cleaved in the thylakoid lumen (step 4). [See R. Dalbey and C. Robinson, 1999, *Trends Biochem. Sci.* **24**:17; R. E. Dalbey and A. Kuhn, 2000, *Ann. Rev. Cell Dev. Biol.* **16**:51; and C. Robinson and A. Bolhuis, 2001, *Nat. Rev. Mol. Cell Biol.* **2**:350.]

cofactor into the thylakoid lumen, a process powered by the H^+ electrochemical gradient normally maintained across the thylakoid membrane. The thylakoid-targeting sequence that directs a protein to this pathway includes two closely spaced arginine residues that are crucial for recognition. Bacterial cells also have a mechanism for translocating folded proteins with a similar arginine-containing sequence across the cytoplasmic membrane, known as the Tat (*twin-arginine translocation*) pathway. The molecular mechanism whereby these large folded globular proteins can be translocated across the thylakoid membrane is currently under intense study.

KEY CONCEPTS of Section 13.4

Targeting of Proteins to Mitochondria and Chloroplasts

- Most mitochondrial and chloroplast proteins are encoded by nuclear genes, synthesized on cytosolic ribosomes, and imported post-translationally into the organelles.
- All the information required to target a precursor protein from the cytosol to the mitochondrial matrix or chloroplast stroma is contained within its N-terminal uptake-targeting sequence. After protein import, the uptake-targeting sequence is removed by proteases within the matrix or stroma.
- Cytosolic chaperones maintain the precursors of mitochondrial and chloroplast proteins in an unfolded state. Only unfolded proteins can be imported into the organelles. Translocation in mitochondria occurs at sites where the outer and inner membranes of the organelles are close together.
- Proteins destined for the mitochondrial matrix bind to receptors on the outer mitochondrial membrane and then are transferred to the general import pore (Tom40) in the outer membrane. Translocation occurs concurrently through the outer and inner membranes, driven by the proton-motive force across the inner membrane and ATP hydrolysis by the Hsc70 ATPase in the matrix (see Figure 13-24).
- Proteins sorted to mitochondrial destinations other than the matrix usually contain two or more targeting sequences, one of which may be an N-terminal matrix-targeting sequence (see Figure 13-26).
- Some mitochondrial proteins destined for the intermembrane space or inner membrane are first imported into the matrix and then redirected; others never enter the matrix but go directly to their final location.
- Protein import into the chloroplast stroma occurs through inner-membrane and outer-membrane translocation channels that are analogous in function to mitochondrial channels, but composed of proteins unrelated in sequence to the corresponding mitochondrial proteins.
- Proteins destined for the thylakoid have secondary targeting sequences. After entry of these proteins into the stroma, cleavage of the stromal-targeting sequences reveals the thylakoid-targeting sequences.

- The four known pathways for moving proteins from the chloroplast stroma to the thylakoid closely resemble translocation across the bacterial cytoplasmic membrane (see Figure 13-29). One of these systems can translocate folded proteins.

13.5 Targeting of Peroxisomal Proteins

Peroxisomes are small organelles bounded by a single membrane. Unlike mitochondria and chloroplasts, peroxisomes lack DNA and ribosomes. Thus all peroxisomal proteins are encoded by nuclear genes, synthesized on ribosomes free in the cytosol, and then incorporated into preexisting or newly generated peroxisomes. As peroxisomes are enlarged by addition of protein (and lipid), they eventually divide, forming new ones, as is the case with mitochondria and chloroplasts.

The size and enzyme composition of peroxisomes vary considerably in different kinds of cells. However, all peroxisomes contain enzymes that use molecular oxygen to oxidize various substrates such as amino acids and fatty acids, breaking them down into smaller components for use in biosynthetic pathways. The hydrogen peroxide (H_2O_2) generated by these oxidation reactions is extremely reactive and potentially harmful to cellular components; however, the peroxisome also contains enzymes, such as catalase, that efficiently convert H_2O_2 into H_2O . In mammals, peroxisomes are most abundant in liver cells, where they constitute about 1–2 percent of the cell volume.

Cytosolic Receptor Targets Proteins with an SKL Sequence at the C-Terminus into the Peroxisomal Matrix

Peroxisomal targeting signals were first identified by testing deletions of peroxisomal proteins for a specific defect in peroxisomal targeting. In one early study, the gene for firefly luciferase was expressed in cultured insect cells and the resulting protein was shown to be properly targeted to the peroxisome. However, expression of a truncated gene missing a small portion of the C-terminus of the protein led to luciferase that failed to be targeted to the peroxisome and remained in the cytoplasm. By testing various mutant luciferase proteins in this system, researchers discovered that the sequence Ser-Lys-Leu (SKL in one-letter code) or a related sequence at the C-terminus was necessary for peroxisomal targeting. Further, addition of the SKL sequence to the C-terminus of a normally cytosolic protein leads to uptake of the altered protein by peroxisomes in cultured cells. All but a few of the many different peroxisomal matrix proteins bear a sequence of this type, known as *peroxisomal-targeting sequence 1*, or simply *PTS1*.

The pathway for import of catalase and other PTS1-bearing proteins into the peroxisomal matrix is depicted in Figure 13-30. The PTS1 binds to a soluble carrier protein in the cytosol (Pex5), which in turn binds to a receptor in the peroxisome

FIGURE 13-30 PTS1-directed import of peroxisomal matrix proteins. Step **1**: Most peroxisomal matrix proteins contain a C-terminal PTS1 uptake-targeting sequence (red) that binds to the cytosolic receptor Pex5. Step **2**: Pex5 with the bound matrix protein forms a multimeric complex with the Pex14 receptor located on the peroxisome membrane. Step **3**: By a process that is not well understood, the matrix protein-Pex5 complex is then transferred into the peroxisomal matrix, where Pex5 dissociates from the matrix protein. Step **4**: Pex5 is then returned to the cytosol by a process that involves the peroxisomal membrane proteins Pex2, Pex10, and Pex12, as well as additional membrane and cytosolic proteins not shown. Note that folded proteins can be imported into peroxisomes and that the targeting sequence is not removed in the matrix. [See P. E. Purdue and P. B. Lazarow, 2001, *Ann. Rev. Cell Dev. Biol.* **17**:701; S. Subramani et al., 2000, *Ann. Rev. Biochem.* **69**:399; and V. Dammal and S. Subramani, 2001, *Cell* **105**:187.]

membrane (Pex14). The protein to be imported then moves across the peroxisomal membrane while still bound to Pex5. The peroxisome import machinery, unlike most systems that mediate protein import into the ER, mitochondria, and chloroplasts, can translocate folded proteins across the membrane. For example, catalase assumes a folded conformation and binds to heme in the cytoplasm before traversing the peroxisomal membrane. Cell-free studies have shown that the peroxisome import machinery can transport large macromolecular objects, including gold particles of about 9 nm in diameter, as long as they have a PTS1 tag attached to them. However, peroxisomal membranes do not appear to contain large stable pore structures, such as the nuclear pore described in the next section. The fundamental mechanism of peroxisomal matrix

protein translocation is not well understood but probably involves the formation of oligomers of Pex5 bound to PTS1-bearing cargo molecules and the Pex14 receptor. There is evidence that the size of the oligomer adjusts according to the size of the PTS1-bearing cargo molecules and that the oligomers dissociate once the complex of Pex5 bound to PTS1-bearing cargo molecule enters the peroxisomal matrix. The dynamic formation of oligomers apparently is the key mechanism by which PTS1-bearing cargo molecules can be accommodated without the formation of large stable pores that would disrupt the integrity of the peroxisomal membrane.

Once the complex of a PTS1-bearing cargo molecule bound to Pex5 enters the matrix, Pex5 dissociates from the peroxisomal matrix protein for recycling back to the cytoplasm. The peroxisomal membrane proteins Pex10, Pex12, and Pex2 form a complex that is crucial for recycling of Pex5. Pex5 is modified by ubiquitination and then is deubiquitinated as part of the recycling process. Since ubiquitin modification of proteins ultimately requires ATP hydrolysis, the energy-dependent recycling of Pex5 may be the step in the import process that uses energy to power unidirectional translocation of cargo molecules across the peroxisomal membrane.

A few peroxisomal matrix proteins such as thiolase are synthesized as precursors with an N-terminal uptake-targeting sequence known as PTS2. These proteins bind to a different cytosolic receptor protein, but otherwise import is thought to occur by the same mechanism as for PTS1-containing proteins.

Peroxisomal Membrane and Matrix Proteins Are Incorporated by Different Pathways

Autosomal recessive mutations that cause defective peroxisome assembly occur naturally in the human population. Such defects can lead to severe developmental defects often associated with craniofacial abnormalities. In Zellweger syndrome and related disorders, for example, the transport of many or all proteins into the peroxisomal matrix is impaired: newly synthesized peroxisomal enzymes remain in the cytosol and are eventually degraded. Genetic analyses of cultured cells from different Zellweger patients and of yeast cells carrying similar mutations have identified more than 20 genes that are required for peroxisome biogenesis.

Studies with peroxisome-assembly mutants have shown that different pathways are used for importing peroxisomal matrix proteins versus inserting proteins into the peroxisomal membrane. For example, analysis of cells from some Zellweger patients led to identification of genes encoding the Pex5-recycling proteins Pex10, Pex12, and Pex2. Mutant cells defective in any one of these proteins cannot incorporate matrix proteins into peroxisomes; nonetheless, the cells contain empty peroxisomes that have a normal complement of peroxisomal membrane proteins (Figure 13-31b). Mutations in any one of three other genes were found to block insertion of peroxisomal membrane proteins as well as import of matrix proteins (Figure 13-31c). These findings demonstrate that one set of proteins translocates soluble proteins

EXPERIMENTAL FIGURE 13-31 Studies reveal different pathways for incorporation of peroxisomal membrane and matrix proteins.

Cells were stained with fluorescent antibodies to PMP70, a peroxisomal membrane protein, or with fluorescent antibodies to catalase, a peroxisomal matrix protein, then viewed in a fluorescent microscope. (a) In wild-type cells, both peroxisomal membrane and matrix proteins are visible as bright foci in numerous peroxisomal bodies. (b) In cells from a Pex12-deficient patient, catalase is distributed uniformly throughout the cytosol, whereas PMP70 is localized normally to peroxisomal bodies. (c) In cells from a Pex3-deficient patient, peroxisomal membranes cannot assemble, and as a consequence, peroxisomal bodies do not form. Thus both catalase and PMP70 are mis-localized to the cytosol. [Courtesy of Stephen Gould, Johns Hopkins University.]

into the peroxisomal matrix, but a different set is required for insertion of proteins into the peroxisomal membrane. This situation differs markedly from that of the ER, mitochondrion, and chloroplast, for which, as we have seen, membrane proteins and soluble proteins share many of the same components for their insertion into these organelles.

Although most peroxisomes are generated by division of preexisting organelles, these organelles can arise *de novo* by the three-stage process depicted in Figure 13-32. In this case, peroxisome assembly begins in the ER. At least two peroxisomal membrane proteins, Pex3 and Pex16, are inserted into the ER membrane by the mechanisms described in Section 13.2. Pex3 and Pex16 then recruit Pex19 to form a specialized region of the ER membrane that can bud off of the ER to form a peroxisomal precursor membrane. Current evidence indicates that peroxisomal membrane protein assembly into mature peroxisomes may also follow the same Pex19-dependent pathway for the *de novo* formation of new peroxisomes from the ER. The insertion of peroxisomal membrane proteins generates membranes that have all the components necessary for import of matrix proteins, leading to the formation of mature, functional peroxisomes.

Division of mature peroxisomes, which largely determines the number of peroxisomes within a cell, depends on still another protein, Pex11. Overexpression of the Pex11 protein causes a large increase in the number of peroxisomes, suggesting that this protein controls the extent of peroxisome division. The small peroxisomes generated by division can be

FIGURE 13-32 Model of peroxisomal biogenesis and division.

The first stage in the *de novo* formation of peroxisomes is the incorporation of peroxisomal membrane proteins into precursor membranes derived from the ER. Pex19 acts as the receptor for membrane-targeting sequences. A complex of Pex3 and Pex16 is required for proper insertion of proteins (e.g., PMP70) into the forming peroxisomal membrane. Insertion of all peroxisomal membrane proteins produces a peroxisomal ghost, which is capable of importing

proteins targeted to the matrix. The pathways for importing PTS1- and PTS2-bearing matrix proteins differ only in the identity of the cytosolic receptor (Pex5 and Pex7, respectively) that binds the targeting sequence (see Figure 13-30). Complete incorporation of matrix proteins yields a mature peroxisome. Although peroxisomes can form *de novo* as just described, under most conditions the proliferation of peroxisomes involves division of mature peroxisomes, a process that depends on the Pex11 protein.

enlarged by incorporation of additional matrix and membrane proteins via the same pathways described previously.

KEY CONCEPTS of Section 13.5

Targeting of Peroxisomal Proteins

- All peroxisomal proteins are synthesized on cytosolic ribosomes and incorporated into the organelle post-translationally.
- Most peroxisomal matrix proteins contain a C-terminal PTS1 targeting sequence; a few have an N-terminal PTS2 targeting sequence. Neither targeting sequence is cleaved after import.
- All proteins destined for the peroxisomal matrix bind to a cytosolic carrier protein, which differs for PTS1- and PTS2-bearing proteins, and then are directed to common import receptor and translocation machinery on the peroxisomal membrane (see Figure 13-30).
- Translocation of matrix proteins across the peroxisomal membrane depends on ATP hydrolysis. Unlike protein import to the ER, mitochondrion, and chloroplast, many peroxisomal matrix proteins fold in the cytosol and traverse the membrane in a folded conformation.
- Proteins destined for the peroxisomal membrane contain different targeting sequences than peroxisomal matrix proteins and are imported by a different pathway.
- Unlike mitochondria and chloroplasts, peroxisomes can arise *de novo* from precursor membranes probably derived from the ER as well as by division of preexisting organelles (see Figure 13-32).

13.6 Transport into and out of the Nucleus

The nucleus is separated from the cytoplasm by two membranes, which form the **nuclear envelope** (see Figure 9-32). The nuclear envelope is continuous with the ER and forms a part of it. Transport of proteins from the cytoplasm into the nucleus and movement of macromolecules, including mRNAs, tRNAs, and ribosomal subunits, out of the nucleus occur through **nuclear pores**, which span both membranes of the nuclear envelope. Import of proteins into the nucleus shares some fundamental features with protein import into other organelles. For example, imported nuclear proteins carry specific targeting sequences known as nuclear localization sequences, or NLSs. However, proteins are imported into the nucleus in a folded state, and thus nuclear import differs fundamentally from protein translocation across the membranes of the ER, mitochondrion, and chloroplast, where proteins are unfolded during translocation. In this section we discuss the main mechanism by which proteins and some ribonuclear proteins such as ribosomes enter and exit the nucleus. We also discuss how mRNAs and other ribonuclear protein complexes are exported from the nucleus by a process that differs mechanistically from nuclear protein import.

Large and Small Molecules Enter and Leave the Nucleus via Nuclear Pore Complexes

Numerous pores perforate the nuclear envelope in all eukaryotic cells. Each nuclear pore is formed from an elaborate structure termed the **nuclear pore complex (NPC)**, which is one of the largest protein assemblages in the cell. The total mass of the pore structure is 60–80 million Da in vertebrates, which is about 16 times larger than a ribosome. An NPC is made up of multiple copies of some 30 different proteins called **nucleoporins**. Electron micrographs of nuclear pore complexes reveal an octagonal, membrane-embedded ring structure that surrounds a largely aqueous pore (Figure 13-33). Eight approximately 100-nm-long filaments extend into the nucleoplasm with the distal ends of these filaments joined by a terminal ring, forming a structure called the **nuclear basket**. Cytoplasmic filaments extend from the cytoplasmic side of the NPC into the cytosol.

Ions, small metabolites, and globular proteins up to about 40 kDa can diffuse passively through the central aqueous region of the nuclear pore complex. However, large proteins and ribonucleoprotein complexes cannot diffuse in and out of the nucleus. Rather, these macromolecules are actively transported through the NPC with the assistance of soluble transporter proteins that bind macromolecules and also interact with nucleoporins. The capacity and efficiency of the NPC for such active transport is remarkable. In one minute, each NPC is estimated to transport 60,000 protein molecules into the nucleus, 50–250 mRNA molecules, 10–20 ribosomal subunits, and 1000 tRNAs out of the nucleus.

In general terms, the nucleoporins are of three types: **structural nucleoporins**, **membrane nucleoporins**, and **FG-nucleoporins**. The structural nucleoporins form the scaffold of the nuclear pore, which is a ring of eightfold symmetry that traverses both membranes of the nuclear envelope, creating an annulus. The membranes of the inner and outer leaflets of the nuclear envelope connect at the NPC by a highly curved region of membrane that contains the embedded membrane nucleoporins (see Figure 13-33b). A set of seven structural nucleoporins forms a Y-shaped structure about the size of the ribosome, known as the **Y-complex**. Sixteen copies of the Y-complex form the basic structural scaffold of the pore, which has bilateral symmetry across the nuclear envelope and eightfold rotational symmetry in the plane of the envelope (see Figure 13-33c). A structural motif repeated several times within the Y-complex is closely related to a structure found in the COPII proteins that drive formation of coated vesicles within cells (see Chapter 14). This primordial relationship between nuclear pore structural proteins and vesicle coat proteins suggests that the two types of membrane coat complexes share a common origin. The basic function of this element may be to form a protein lattice that, in a complex with membrane nucleoporins, deforms the membrane into a highly curved structure.

The FG-nucleoporins, which line the channel of the nuclear pore complex and also are found associated with the nuclear basket and the cytoplasmic filaments, contain multiple repeats of short hydrophobic sequences that are rich in

FIGURE 13-33 Nuclear pore complex at different levels of resolution. (a) Visualized by scanning electron microscopy, nuclear envelopes from the large nuclei of *Xenopus* oocytes. *Top*: View of the cytoplasmic face reveals octagonal shape of membrane-embedded portion of nuclear pore complexes. *Bottom*: View of the nucleoplasmic face shows the nuclear basket that extends from the membrane portion. (b) Cutaway model of the pore complex showing the major structural features formed by membrane nucleoporins, structural nucleoporins, and FG-nucleoporins. (c) Sixteen copies of the Y-complex forms a major part of the structural scaffold of the nuclear pore complex. The three-dimensional structure of the Y-complex is modeled into the pore structure. Note the twofold symmetry across the double

membrane of the nucleus (*left*) and the eightfold rotational symmetry around the axis of the pore (*right*). (d) The FG-nucleoporins have extended disordered structures that are composed of repeats of the sequence Phe–Gly interspersed with hydrophilic regions (*left*). The FG-nucleoporins are most abundant in the central part of the pore, and the FG-repeat sequences are thought to fill the central channel with a gel-like matrix (*right*). [Part (a) from V. Doye and E. Hurt, 1997, *Curr. Opin. Cell Biol.* **9**:401, courtesy of M. W. Goldberg and T. D. Allen. Part (b) adapted from M. P. Rout and J. D. Atchison, 2001, *J. Biol. Chem.* **276**:16593. phenylalanine (F) and glycine (G) residues (FG-repeats). The hydrophobic FG-repeats are thought to occur in regions of extended, otherwise hydrophilic polypeptide chains that fill the central transporter channel. The FG-nucleoporins are essential for the function of the NPC; however, the NPC remains functional even if up to half of the FG-repeats have been deleted. The FG-nucleoporins are thought to form a flexible gel-like matrix with bulk properties that allow the diffusion of small molecules while excluding unchaperoned hydrophilic proteins larger than 40 kDa (see Figure 13-33d).

Nuclear Transport Receptors Escort Proteins Containing Nuclear-Localization Signals into the Nucleus

All proteins found in the nucleus—such as histones, transcription factors, and DNA and RNA polymerases—are synthesized in the cytoplasm and imported into the nucleus through nuclear pore complexes. Such proteins contain a *nuclear-localization signal* (NLS) that directs their selective transport into the nucleus. NLSs were first discovered through the analysis of mutants of the gene for large T-antigen encoded by simian virus 40 (SV40). The wild-type form of large T-antigen is localized to the nucleus in virus-infected cells, whereas some mutated forms of large T-antigen accumulate in the cytoplasm (Figure 13-34). The mutations responsible for this altered cellular localization all occur within a specific seven-residue sequence rich in basic

amino acids near the C-terminus of the protein: Pro-Lys-Lys-Lys-Arg-Lys-Val. Experiments with engineered hybrid proteins in which this sequence was fused to a cytosolic protein demonstrated that it directs transport into the nucleus and consequently functions as an NLS. NLS sequences subsequently were identified in numerous other proteins imported into the nucleus. Many of these are similar to the basic NLS in SV40 large T-antigen, whereas other NLSs are chemically quite different. For instance, an NLS in the RNA-binding protein hnRNP A1 is hydrophobic. Thus there must be multiple mechanisms for the recognition of these very different sequences.

Early work on the mechanism of nuclear import showed that proteins containing a basic NLS, similar to the one in SV40 large T-antigen, will be efficiently transported into isolated nuclei if they are provided with a cytosolic extract (Figure 13-35). Using this assay system, researchers purified two

EXPERIMENTAL FIGURE 13-34 Nuclear-localization signal (NLS) directs proteins to the cell nucleus. Cytoplasmic proteins can be localized to the nucleus when they are fused to a nuclear localization signal. (a) Normal pyruvate kinase, visualized by immunofluorescence after cultured cells were treated with a specific antibody (yellow), is localized to the cytoplasm. This very large cytosolic protein functions in carbohydrate metabolism. (b) When a chimeric pyruvate kinase protein containing the SV40 NLS at its N-terminus was expressed in cells, it was localized to the nucleus. The chimeric protein was expressed from a transfected engineered gene produced by fusing a viral gene fragment encoding the SV40 NLS to the pyruvate kinase gene. [From D. Kalderon et al., 1984, *Cell* 39:499, courtesy of Dr. Alan Smith.]

(a) Effect of digitonin

(b) Nuclear import by permeabilized cells

EXPERIMENTAL FIGURE 13-35 Cytosolic proteins are required for nuclear transport. The failure of nuclear transport to occur in permeabilized cultured cells in the absence of lysate demonstrates the involvement of soluble cytosolic components in the process. (a) Phase-contrast micrographs of untreated and digitonin-permeabilized HeLa cells. Treatment of a monolayer of cultured cells with the mild, nonionic detergent digitonin permeabilizes the plasma membrane so that cytosolic constituents leak out but leaves the nuclear envelope and NPCs intact. (b) Fluorescence micrographs of digitonin-permeabilized HeLa cells incubated with a fluorescent protein chemically coupled to a synthetic SV40 T-antigen NLS peptide in the presence and absence of cytosol (lysate). Accumulation of this transport substrate in the nucleus occurred only when cytosol was included in the incubation (*right*). [From S. Adam et al., 1990, *J. Cell Biol.* 111:807, courtesy of Dr. Larry Gerace.]

FIGURE 13-36 Nuclear import. Mechanism for nuclear import of “cargo” proteins. In the cytoplasm (top), a free nuclear transport receptor (importin) binds to the NLS of a cargo protein, forming a bimolecular cargo complex. The cargo complex diffuses through the NPC by transiently interacting with FG-nucleoporins. In the nucleoplasm, Ran-GTP binds to the importin, causing a conformational change that decreases its affinity for the NLS and releasing the cargo. To support another cycle of import, the exportin-Ran-GTP complex is transported back to the cytoplasm. A GTPase-accelerating protein (GAP) associated with the cytoplasmic filaments of the NPC stimulates Ran to hydrolyze the bound GTP. This generates a conformational change that causes dissociation from the nuclear transport receptor, which can then initiate another round of import. Ran-GDP is returned to the nucleoplasm, where a guanine nucleotide-exchange factor (GEF) causes release of GDP and rebinding of GTP.

required cytosolic components: Ran and a nuclear transport receptor. *Ran* is a small monomeric G protein that exists in either GTP- or GDP-bound conformations (see Figure 3-32). The *nuclear transport receptor* binds to both the NLS on a cargo protein to be transported into the nucleus and to FG-repeats on nucleoporins. By a physical process that is not well understood, by binding transiently to FG-repeats, nuclear transport receptors have the ability to rapidly traverse the FG-repeat-containing matrix in the central channel of the nuclear pore, whereas proteins of similar size that lack this property are excluded from the central channel. Nuclear transport receptors can be monomeric, with a single polypeptide that can bind to both an NLS and FG-repeats, or they can be dimeric, with one subunit binding to the NLS and the other binding to FG-repeats.

The mechanism for import of cytoplasmic cargo proteins mediated by a nuclear import receptor is shown in Figure 13-36. Free nuclear transport receptor in the cytoplasm binds to its cognate NLS in a cargo protein, forming an importin-cargo complex. The cargo complex then translocates through the NPC channel as the nuclear transport receptor interacts with FG-repeats. The cargo complex rapidly reaches the nucleoplasm, and there the nuclear transport receptor interacts with Ran-GTP, causing a conformational change in the nuclear transport receptor that displaces the NLS, releasing the cargo protein into the nucleoplasm. The nuclear transport receptor-Ran-GTP complex then diffuses back through the NPC. Once the nuclear transport receptor-Ran-GTP complex

reaches the cytoplasmic side of the NPC, Ran interacts with a specific *GTPase-activating protein (Ran-GAP)* that is a component of the NPC cytoplasmic filaments. This stimulates Ran to hydrolyze its bound GTP to GDP, causing it to convert to a conformation that has low affinity for the nuclear transport receptor, so that the free nuclear transport receptor is released into the cytoplasm, where it can participate in another cycle of import. Ran-GDP travels back through the pore to the nucleoplasm, where it encounters a specific *guanine nucleotide-exchange factor (Ran-GEF)* that causes Ran to release its bound GDP in favor of GTP. The net result of this series of reactions is the coupling of the hydrolysis of GTP to the transfer of an NLS-bearing protein from the cytoplasm to the nuclear interior, thus providing a driving force for nuclear transport.

Although the nuclear transport receptor-cargo complex travels through the pore by random diffusion, the overall process of transport of cargo into the nucleus is unidirectional. Because of the rapid dissociation of the import complex when it reaches the nucleoplasm, there is a concentration gradient of the nuclear transport receptor-cargo complex across the NPC: high in the cytoplasm, where the complex assembles, and low in the nucleoplasm, where it dissociates. This concentration gradient is responsible for the unidirectional nature of nuclear import. A similar concentration gradient is responsible for driving the nuclear transport receptor in the nucleus back into the cytoplasm. The concentration of the nuclear transport receptor-Ran-GTP complex is higher in the nucleoplasm, where

it assembles, than on the cytoplasmic side of the NPC, where it dissociates. Ultimately, the direction of the transport processes depends on the asymmetric distribution of the Ran-GEF and the Ran-GAP. Ran-GEF in the nucleoplasm maintains Ran in the Ran·GTP state, where it promotes dissociation of the cargo complex. Ran-GAP on the cytoplasmic side of the NPC converts Ran·GTP to Ran·GDP, dissociating the nuclear transport receptor-Ran·GTP complex and releasing free nuclear transport receptor into the cytosol.

A Second Type of Nuclear Transport Receptors Escort Proteins Containing Nuclear-Export Signals out of the Nucleus

A very similar mechanism is used to export proteins, tRNAs, and ribosomal subunits from the nucleus to the cytoplasm. This mechanism initially was elucidated from studies of certain ribonuclear protein complexes that “shuttle” between the nucleus and the cytoplasm. Such “shuttling” proteins contain a *nuclear-export signal* (NES) that stimulates their export from the nucleus to the cytoplasm through nuclear pores, in addition to an NLS that results in their uptake into the nucleus. Experiments with engineered hybrid genes encoding a nucleus-restricted protein fused to various segments of a protein that shuttles in and out of the nucleus have identified at least three different classes of NESs: a leucine-rich sequence found in PKI (an inhibitor of protein kinase A) and in the Rev protein of human immunodeficiency virus (HIV), as well as two sequences identified in two different heterogeneous ribonucleoprotein particles (hnRNPs). The functionally significant structural features that specify nuclear export remain poorly understood.

The mechanism whereby shuttling proteins are exported from the nucleus is best understood for those containing a leucine-rich NES. According to the current model, shown in Figure 13-37a, a specific nuclear transport receptor, in the nucleus, called exportin 1, first forms a complex with Ran·GTP and then binds the NES in a cargo protein. Binding of exportin 1 to Ran·GTP causes a conformational change in exportin 1 that increases its affinity for the NES so that a *trimolecular cargo complex* is formed. Like other nuclear transport receptors, exportin 1 interacts transiently with FG-repeats in FG-nucleoporins and diffuses through the NPC. The cargo complex dissociates when it encounters the Ran-GAP in the NPC cytoplasmic filaments, which stimulates Ran to hydrolyze the bound GTP, shifting it into a conformation that has low affinity for exportin 1. The released exportin 1 changes conformation to a structure that has low affinity for the NES, releasing the cargo into the cytosol. The direction of the export process is driven by this dissociation of the cargo from exportin 1 in the cytoplasm, which causes a concentration gradient of the cargo complex across the NPC that is high in the nucleoplasm and low in the cytoplasm. Exportin 1 and the Ran·GDP are then transported back into the nucleus through an NPC.

By comparing this model for nuclear export with that in Figure 13-36 for nuclear import, we can see one obvious

difference: Ran·GTP is part of the cargo complex during export but not during import. Apart from this difference, the two transport processes are remarkably similar. In both processes, association of a nuclear transport receptor with Ran·GTP in the nucleoplasm causes a conformational change that affects its affinity for the transport signal. During import, the interaction causes release of the cargo, whereas during export, the interaction promotes association with the cargo. In both export and import, stimulation of Ran·GTP hydrolysis in the cytoplasm by Ran-GAP produces a conformational change in Ran that releases the transport signal receptor. During nuclear export, the cargo is also released. Localization of the Ran-GAP and -GEF to the cytoplasm and nucleus, respectively, is the basis for the unidirectional transport of cargo proteins across the NPC.

In keeping with their similarity in function, the two types of nuclear transport receptors are highly homologous in sequence and structure. The family of nuclear transport receptors has 14 members in yeast and more than 20 in mammalian cells. The NESs or NLSs to which they bind have been determined for only a fraction of them. Some individual nuclear transport receptors function in both import and export.

A similar shuttling mechanism has been shown to export other cargoes from the nucleus. For example, exportin-t functions to export tRNAs. Exportin-t binds fully processed tRNAs in a complex with Ran·GTP that diffuses through NPCs and dissociates when it interacts with Ran-GAP in the NPC cytoplasmic filaments, releasing the tRNA into the cytosol. A Ran-dependent process is also required for the nuclear export of ribosomal subunits through NPCs once the protein and RNA components have been properly assembled in the nucleolus. Likewise, certain specific mRNAs that associate with particular hnRNP proteins can be exported by a Ran-dependent mechanism.

Most mRNAs Are Exported from the Nucleus by a Ran-Independent Mechanism

Once the processing of an mRNA is completed in the nucleus, it remains associated with specific hnRNP proteins in a *messenger ribonuclear protein complex*, or mRNP. The principal transporter of mRNPs out of the nucleus is the **mRNP exporter**, a heterodimeric protein composed of a large subunit called *nuclear export factor 1* (NXF1) and a small subunit, *nuclear export transporter 1* (NXT1). Multiple NXF1/NXT1 dimers bind to nuclear mRNPs through cooperative interactions with the RNA and other mRNP adapter proteins that associate with nascent pre-mRNAs during transcription elongation and pre-mRNA processing. In many respects, NXF1/NXT1 acts like a nuclear transport receptor that binds to an NLS or NES in the sense that both subunits interact with the FG-domains of FG-nucleoporins, allowing them to diffuse through the central channel of the NPC.

The process of mRNP export does not require Ran, and thus the unidirectional transport of mRNA out of the nucleus requires a source of energy other than GTP hydrolysis by Ran. Once the mRNP-NXF1/NXT1 complex reaches the

FIGURE 13-37 Ran-dependent and

Ran-independent nuclear export.

(a) Ran-dependent mechanism for nuclear export of cargo proteins containing a leucine-rich nuclear-export signal (NES). In the nucleoplasm (bottom), the protein exportin 1 binds cooperatively to the NES of the cargo protein to be transported and to Ran-GTP. After the resulting cargo complex diffuses through an NPC via transient interactions with FG repeats in FG-nucleoporins, the GAP associated with the NPC cytoplasmic filaments stimulates GTP hydrolysis, converting Ran-GTP to Ran-GDP. The accompanying conformational change in Ran leads to dissociation of the complex. The NES-containing cargo protein is released into the cytosol, whereas exportin 1 and Ran-GDP are transported back into the nucleus through NPCs. Ran-GEF in the nucleoplasm then stimulates conversion of Ran-GDP to Ran-GTP. (b) Ran-independent nuclear export of mRNAs. The heterodimeric NXF1/NXT1 complex binds to mRNA-protein complexes (mRNPs) in the nucleus. NXF1/NXT1 act as a nuclear export factor and directs the associated mRNP to the central channel of the NPC by transiently interacting with FG-nucleoporins. An RNA helicase (Dbp5) located on the cytoplasmic side of the NPC removes NXF1 and NXT1 from the mRNA in a reaction that is powered by ATP hydrolysis. Free NXF1 and NXT1 proteins are recycled back into the nucleus by the Ran-dependent import process depicted in Figure 13-36.

cytoplasmic side of the NPC, NXF1 and NXT1 dissociate from the mRNP with the help of the RNA helicase, Dbp5, which associates with cytoplasmic NPC filaments. Recall that RNA helicases use the energy derived from hydrolysis of ATP to move along RNA molecules, separating double-stranded

RNA chains and dissociating RNA-protein complexes (Chapter 4). This leads to the simple idea that Dbp5, which associates with the cytoplasmic side of the nuclear pore complex, acts as an ATP-driven motor to remove NXF1/NXT1 from the mRNP complexes as they emerge on the cytoplasmic side

of the NPC. The assembly of NXF1/NXT1 onto mRNPs on the nucleoplasmic side of the NPC and the subsequent ATP-dependent disassembly of NXF1/NXT1 from mRNPs on the cytoplasmic side of the NPC creates a concentration gradient of mRNP-NXF1/NXT1 which drives unidirectional export. After being removed from the mRNP, the free NXF1 and NXT1 proteins that have been stripped from the mRNA by Dbp5 helicase are imported back into the nucleus by a process that depends on Ran and a nuclear transport receptor (Figure 13-37b).

In Ran-dependent nuclear export (discussed in the previous subsection), hydrolysis of GTP by Ran on the cytoplasmic side of the NPC causes dissociation of the nuclear transport receptor from its cargo. In basic outline, the *Ran-independent* nuclear export discussed here operates by a similar mechanism except that Dbp5p on the cytosolic side of the NPC uses hydrolysis of ATP to dissociate the mRNP exporter from mRNA.

KEY CONCEPTS of Section 13.6

Transport into and out of the Nucleus

- The nuclear envelope contains numerous nuclear pore complexes (NPCs), which are large, complicated structures composed of multiple copies of 30 proteins called *nucleoporins* (see Figure 13-33). FG-nucleoporins, which contain multiple repeats of a short hydrophobic sequence (FG-repeats), line the central transporter channel and play a role in transport of all macromolecules through nuclear pores.
- Transport of macromolecules larger than 20–40 kDa through nuclear pores requires the assistance of nuclear transport receptors that interact with both the transported molecule and FG-repeats of FG-nucleoporins.
- Proteins imported to or exported from the nucleus contain a specific amino acid sequence that functions as a nuclear-localization signal (NLS) or a nuclear-export signal (NES). Nucleus-restricted proteins contain an NLS but not an NES, whereas proteins that shuttle between the nucleus and cytoplasm contain both signals.
- Several different types of NES and NLS have been identified. Each type of nuclear-transport signal is thought to interact with a specific nuclear transport protein belonging to a family of homologous proteins.
- A cargo protein bearing an NES or NLS translocates through nuclear pores bound to its cognate nuclear transport protein. The transient interactions between nuclear transport receptors and FG-repeats allow very rapid diffusion of nuclear transport protein-cargo complex through the central channel of the NPC, which is filled with a hydrophobic matrix of FG-repeats.
- The unidirectional nature of protein export and import through nuclear pores results from participation of Ran, a monomeric G protein that exists in different conformations when bound to GTP or GDP. Localization of the Ran guanine nucleotide-exchange factor (GEF) in the nucleus and of Ran

GTPase-activating protein (GAP) in the cytoplasm creates a gradient with high Ran·GTP in the nucleoplasm and Ran·GDP in the cytoplasm. The interaction of import cargo complexes with the Ran·GTP in the nucleoplasm causes dissociation of the complex, releasing the cargo into the nucleoplasm (see Figure 13-36), whereas the assembly of export cargo complexes is stimulated by interaction with Ran·GTP in the nucleoplasm (see Figure 13-37).

- Most mRNPs are exported from the nucleus by binding to a heterodimeric mRNP exporter in the nucleoplasm that interacts with FG-repeats. The direction of transport (nucleus to cytoplasm) results from the action of an RNA helicase associated with the cytoplasmic filaments of the nuclear pore complexes that removes the heterodimeric mRNP exporter once the transport complex has reached the cytoplasm.

Perspectives for the Future

As we have seen in this chapter, we now understand many aspects of the basic processes responsible for selectively transporting proteins into the endoplasmic reticulum (ER), mitochondrion, chloroplast, peroxisome, and nucleus. Biochemical and genetic studies, for instance, have identified signal sequences responsible for targeting proteins to the correct organelle membrane and the membrane receptors that recognize these signal sequences. We also have learned much about the underlying mechanisms that translocate proteins across organelle membranes and have determined whether energy is used to push or pull proteins across the membrane in one direction, the type of channel through which proteins pass, and whether proteins are translocated in a folded or an unfolded state. Nonetheless, fundamental questions remain unanswered; probably the most puzzling is how fully folded proteins move across a membrane.

The peroxisomal import machinery provides one example of the translocation of folded proteins. It not only is capable of translocating fully folded proteins with bound cofactors into the peroxisomal matrix, it can even direct the import of a large gold particle decorated with a (PTS1) peroxisomal targeting peptide. Some researchers have speculated that the mechanism of peroxisomal import may be related to that of nuclear import, the best-understood example of post-translational translocation of folded proteins. Both the peroxisomal and nuclear import machinery can transport folded molecules of very divergent sizes, and both appear to involve a component that cycles between the cytosol and the organelle interior—the Pex5 PTS1 receptor in the case of peroxisomal import and the Ran-importin complex in the case of nuclear import. However, there also appear to be crucial differences between the two translocation processes. For example, nuclear pores represent large, stable macromolecular assemblies that are readily observed by electron microscopy, whereas analogous porelike structures have not been observed in the peroxisomal membrane. Moreover, small

molecules can readily pass through nuclear pores, whereas peroxisomal membranes maintain a permanent barrier to the diffusion of small hydrophilic molecules. Taken together, these observations suggest that peroxisomal import may require an entirely new type of translocation mechanism.

The evolutionarily conserved mechanisms for translocating folded proteins across the cytoplasmic membrane of bacterial cells and across the thylakoid membrane of chloroplasts also are poorly understood. A better understanding of all of these processes for translocating folded proteins across a membrane will likely hinge on future development of *in vitro* translocation systems that allow investigators to define the biochemical mechanisms driving translocation and to identify the structures of trapped translocation intermediates.

Compared with our understanding of how soluble proteins are translocated into the ER lumen and mitochondrial matrix, our understanding of how targeting sequences specify the topology of multipass membrane proteins is quite elementary. For instance, we do not know how the translocon channel accommodates polypeptides that are oriented differently with respect to the membrane, nor do we understand how local polypeptide sequences interact with the translocon channel both to set the orientation of transmembrane spans and to signal for lateral passage into the membrane bilayer. A better understanding of how the amino acid sequences of membrane proteins can specify membrane topology will be crucial for decoding the vast amount of structural information for membrane proteins contained within databases of genomic sequences.

A more detailed understanding of all translocation processes should continue to emerge from genetic and biochemical studies, both in yeasts and in mammals. These studies will undoubtedly reveal additional key proteins involved in the recognition of targeting sequences and in the translocation of proteins across lipid bilayers. Finally, the structural studies of translocon channels will likely be extended in the future to reveal, at resolutions on the atomic scale, the conformational states that are associated with each step of the translocation cycle.

Key Terms

cotranslational translocation 582	N-linked oligosaccharides 594
dislocation 600	nuclear pore complex (NPC) 615
dolichol phosphate 595	nuclear transport receptor 618
FG-nucleoporins 615	O-linked oligosaccharides 594
general import pore 604	post-translational translocation 584
hydropathy profile 593	protein disulfide isomerase 597
microsomes 580	
molecular chaperones 585	
multipass membrane proteins 588	

Ran protein 618	stop-transfer anchor sequence 588
rough ER 580	topogenic sequences 587
signal-anchor sequence 588	topology (membrane protein) 587
signal-recognition particle (SRP) 582	translocon 583
signal (uptake-targeting) sequences 579	trimolecular cargo complex 619
single-pass membrane proteins 587	unfolded-protein response 599

Review the Concepts

1. The following results were obtained in early studies on the translation of secretory proteins. Based on what we now know of this process, explain the reason why each result was observed. (a) An *in vitro* translation system consisting only of mRNA and ribosomes resulted in secretory proteins that were larger than the identical protein when translated in a cell. (b) A similar system that also included microsomes produced secretory proteins that were identical in size to those found in a cell. (c) When the microsomes were added after *in vitro* translation, the synthesized proteins were again larger than those made in a cell.
2. Describe the source or sources of energy needed for unidirectional translocation across the membrane in (a) cotranslational translocation into the endoplasmic reticulum (ER); (b) post-translational translocation into the ER; (c) translocation into the mitochondrial matrix.
3. Translocation into most organelles usually requires the activity of one or more cytosolic proteins. Describe the basic function of three different cytosolic factors required for translocation into the ER, mitochondria, and peroxisomes, respectively.
4. Describe the typical principles used to identify topogenic sequences within proteins and how these can be used to develop computer algorithms. How does the identification of topogenic sequences lead to prediction of the membrane arrangement of a multipass protein? What is the importance of the arrangement of positive charges relative to the membrane orientation of a signal-anchor sequence?
5. An abundance of misfolded proteins in the ER can result in the activation of the unfolded protein response (UPR) and ER-associated degradation (ERAD) pathways. UPR decreases the amount of unfolded proteins by altering gene expression of what type of genes? What is one manner in which ERAD may identify misfolded proteins? Why is dislocation of these misfolded proteins to the cytoplasm necessary?
6. Temperature-sensitive yeast mutants have been isolated that block each of the enzymatic steps in the synthesis of the dolichol-oligosaccharide precursor for N-linked glycosylation. Propose an explanation for why mutations that block synthesis of the intermediate with the structure dolichol-PP-(GlcNAc)₂Man₅ completely prevent addition of N-linked oligosaccharide chains to secretory proteins, whereas mutations

that block conversion of this intermediate into the completed precursor—dolichol-PP-(GlcNAc)₂Man₉Glc₃—allow the addition of *N*-linked oligosaccharide chains to secretory glycoproteins.

7. Name four different proteins that facilitate the modification and/or folding of secretory proteins within the lumen of the ER. Indicate which of these proteins covalently modifies substrate proteins and which brings about only conformational changes in substrate proteins.

8. Describe what would happen to the precursor of a mitochondrial matrix protein in the following types of mitochondrial mutants: (a) a mutation in the Tom22 signal receptor; (b) a mutation in the Tom70 signal receptor; (c) a mutation in the matrix Hsc70; and (d) a mutation in the matrix signal peptidase.

9. Describe the similarities and differences between the mechanism of import into the mitochondrial matrix and the chloroplast stroma.

10. Design a set of experiments using chimeric proteins, composed of a mitochondrial precursor protein fused to dihydrofolate reductase (DHFR), that could be used to determine how much of the precursor protein must protrude into the mitochondrial matrix in order for the matrix-targeting sequence to be cleaved by the matrix-processing protease.

11. Peroxisomes contain enzymes that use molecular oxygen to oxidize various substrates, but in the process hydrogen peroxide—a compound that can damage DNA and proteins—is formed. What is the name of the enzyme responsible for the breakdown of hydrogen peroxide to water? What is the mechanism of the import of this protein into the peroxisome, and what proteins are involved?

12. Suppose that you have identified a new mutant cell line that lacks functional peroxisomes. Describe how you could determine experimentally whether the mutant is primarily defective for insertion/assembly of peroxisomal membrane proteins or matrix proteins.

13. The nuclear import of proteins larger than 40 kDa requires the presence of what amino acid sequence? Describe the mechanism of nuclear import. How are nuclear transport receptors able to get through the nuclear pore complex?

14. Why is localization of Ran-GAP in the nucleus and Ran-GEF in the cytoplasm necessary for unidirectional transport of cargo proteins containing an NES?

Analyze the Data

1. Imagine that you are evaluating the early steps in translocation and processing of the secretory protein prolactin. By using an experimental approach similar to that shown in Figure 13-7, you can use truncated prolactin mRNAs to control the length of nascent prolactin polypeptides that are synthesized. When prolactin mRNA that lacks a chain-termination (stop) codon is translated *in vitro*, the newly synthesized

polypeptide ending with the last codon included on the mRNA will remain attached to the ribosome, thus allowing a polypeptide of defined length to extend from the ribosome. You have generated a set of mRNAs that encode segments of the N-terminus of prolactin of increasing length, and each mRNA can be translated *in vitro* by a cytosolic translation extract containing ribosomes, tRNAs, aminoacyl-tRNA synthetases, GTP, and translation initiation and elongation factors. When radiolabeled amino acids are included in the translation mixture, only the polypeptide encoded by the added mRNA will be labeled. After completion of translation, each reaction mixture was resolved by SDS polyacrylamide gel electrophoresis, and the labeled polypeptides were identified by autoradiography.

a. The autoradiogram depicted below shows the results of an experiment in which each translation reaction was carried out either in the presence (+) or the absence (–) of microsomal membranes. Based on the gel mobility of peptides synthesized in the presence or absence of microsomes, deduce how long the prolactin nascent chain must be in order for the prolactin signal peptide to enter the ER lumen and to be cleaved by signal peptidase. (Note that microsomes carry significant quantities of SRP weakly bound to the membranes.)

b. Given this length, what can you conclude about the conformational state(s) of the nascent prolactin polypeptide when it is cleaved by signal peptidase? The following lengths will be useful for your calculation: the prolactin signal sequence is cleaved after amino acid 31; the channel within the ribosome occupied by a nascent polypeptide is about 150 Å long; a membrane bilayer is about 50 Å thick; in polypeptides with an α -helical conformation, one residue extends 1.5 Å, whereas in fully extended polypeptides, one residue extends about 3.5 Å.

c. The experiment described in part (a) is carried out in an identical manner except that microsomal membranes are not present during translation but are added after translation is complete. In this case none of the samples shows a difference in mobility in the presence or absence of microsomes. What can you conclude about whether prolactin can be translocated into isolated microsomes post-translationally?

d. In another experiment, each translation reaction was carried out in the presence of microsomes, and then the microsomal membranes and bound ribosomes were separated

from free ribosomes and soluble proteins by centrifugation. For each translation reaction, both the total reaction (T) and the membrane fraction (M) were resolved in neighboring gel lanes. Based on the amounts of labeled polypeptide in the membrane fractions in the autoradiogram depicted below, deduce how long the prolactin nascent chain must be in order for ribosomes engaged in translation to engage the SRP and thereby become bound to microsomal membranes.

2. Recently, researchers discovered that treating mammalian cells with juniferdin, a plant-derived compound, affects protein secretion, and have reported that the target of this drug is *protein disulfide isomerase* (PDI). In the following experiment, cultured pancreatic β -cells were treated with juniferdin and protein lysates were isolated and compared to lysates from untreated cells using immunoblot analysis. Probing blots with antibodies against PDI (57 kDa), actin (43 kDa) and pro-insulin (9.8 kDa), show the following:

a. Given that approximately the same amount of protein was loaded in each lane, as evidenced by the actin signals, how do you explain the fact that the PDI levels also appear about the same, while most of the pro-insulin remains accumulated in the juniferdin-treated cells?

b. To confirm your results, protein lysates of juniferdin-treated and untreated cells were separated by SDS-PAGE and blotted to membranes and then probed with antibodies against Ire1 and Hac1.

Label each blot with the antibody that was used for the analysis. How do you explain the increase in the intensity of the signal seen in the juniferdin-treated cells in blot B?

c. An immunocytochemistry and fluorescence microscopy analysis was undertaken with the antibody used in blot B and a secondary antibody labeled with rhodamine (red). Since juniferdin specifically affects PDI, a resident rough ER (RER) protein, how do you explain the localization of the signal in the nucleus?

3. Antibody labeling of proteins like that used in immunofluorescence analysis can be applied to electron microscopy, but instead of using fluorescent labels attached to antibodies, investigators use gold particles that are electron dense and appear as uniform dots in an electron micrograph. Furthermore, by varying the size of the gold particles (e.g., 5 nm vs 10 nm), one can identify the localization of more than one protein in the cell.

a. Using this approach, investigators have determined the subcellular localization of Tim and Tom proteins used for protein import into mitochondria. In the drawing of the results below, label the gold particles showing the localization of Tim44 and Tom40. What made you come to these conclusions?

b. Genetically engineering the N-terminus of alcohol dehydrogenase (ADH) onto a cytosolic protein alters that protein's localization. The following blot was seen when cells were transfected with an ADH-actin chimeric construct, and proteins were isolated from the cytosol and mitochondria. Antibodies against actin (43 kDa), the cytosolic protein GAPDH (37 kDa), and the mitochondrial inner membrane protein succinate dehydrogenase A (72 kDa), were used in the analysis.

How do you explain the presence of actin in two distinct sub-cellular pools of protein? How do you explain it being the same molecular mass in both pools? If the blot were stripped and re-probed with an antibody against the N-terminus of alcohol dehydrogenase; where would you expect to find the signal?

c. Cyanide is toxic to cells because it inhibits a specific mitochondrial protein complex that is responsible for producing ATP. An experiment like that described above was repeated and the results compared to those for cells exposed to hydrogen cyanide. The following are the results from the immunoblot analysis:

How do you explain the apparent shift in the molecular mass of actin in the mitochondrial fraction of cyanide-treated cells? Note that there is a similar shift in the mass of the succinate dehydrogenase A control. What would you expect to see on blots if cyanide-treated cells were supplemented with ATP?

Scanning electron micrograph showing the formation of clathrin-coated vesicles on the cytosolic face of the plasma membrane. [John Heuser, Washington University School of Medicine.]

Vesicular Traffic, Secretion, and Endocytosis

In the previous chapter we explored how proteins are targeted to and translocated across the membranes of several different intracellular organelles, including the endoplasmic reticulum, mitochondria and chloroplasts, peroxisomes, and the nucleus. In this chapter we turn our attention to the **secretory pathway** and the mechanisms of vesicular traffic that allow proteins to be secreted from the cell or delivered to the plasma membrane and the lysosome. We will also discuss the related processes of endocytosis and autophagy, which deliver proteins and small molecules from either outside the cell or from the cytoplasm to the interior of the lysosome for degradation.

The secretory pathway carries both soluble and membrane proteins from the ER to their final destination at the cell surface or in the lysosome. Proteins delivered to the plasma membrane include cell-surface receptors, transporters for nutrient uptake, and ion channels that maintain the proper ionic and electrochemical balance across the plasma membrane. Such membrane proteins, once they reach the plasma membrane, become embedded within it. Soluble secreted proteins also follow the secretory pathway to the cell surface, but instead of remaining embedded in the membrane they are released into the aqueous extracellular environment. Examples of secreted proteins are digestive enzymes, peptide hormones, serum proteins, and collagen. As described in Chapter 9, the lysosome is an organelle with

an acidic interior that is generally used for degradation of unneeded proteins and the storage of small molecules such as amino acids. Accordingly, the types of proteins delivered to the lysosomal membrane include subunits of the V-class proton pump that pumps H^+ from the cytosol into the acidic lumen of the lysosome, as well as transporters that release small molecules stored in the lysosome into the cytoplasm. Soluble proteins delivered by this pathway include lysosomal digestive enzymes such as proteases, glycosidases, phosphatases, and lipases.

In contrast to the secretory pathway, which allows proteins to be targeted to the cell surface, the **endocytic pathway** is used to take up substances from the cell surface and move them into the interior of the cell. The endocytic pathway is used to ingest certain nutrients that are too large to be transported across the plasma membrane by one of the transport mechanisms discussed in Chapter 11. For example, the endocytic pathway is utilized in the uptake of cholesterol carried in LDL particles, and iron atoms carried by the iron-binding protein transferrin. In addition, the endocytic pathway can be used to remove receptor proteins from the cell surface as a way to down-regulate their activity.

A single unifying principle governs all protein trafficking in the secretory and endocytic pathways: transport of membrane and soluble proteins from one membrane-bounded compartment to another is mediated by **transport vesicles**

OVERVIEW ANIMATION: Protein Secretion

FIGURE 14-1 Overview of the secretory and endocytic pathways of protein sorting. *Secretory pathway:*

Synthesis of proteins bearing an ER signal sequence is completed on the rough ER **1**, and the newly made polypeptide chains are inserted into the ER membrane or cross it into the lumen (Chapter 13). Some proteins (e.g., ER enzymes or structural proteins) remain within the ER. The remainder are packaged into transport vesicles **2** that bud from the ER and fuse to form new *cis*-Golgi cisternae. Missorted ER-resident proteins and vesicle membrane proteins that need to be reused are retrieved to the ER by vesicles **3** that bud from the *cis*-Golgi and fuse with the ER. Each *cis*-Golgi cisterna, with its protein content, physically moves from the *cis* to the *trans* face of the Golgi complex **4** by a nonvesicular process called cisternal maturation. Retrograde transport vesicles **5** move Golgi-resident proteins to the proper Golgi compartment. In all cells, certain soluble proteins move to the cell surface in transport vesicles **6** and are secreted continuously (constitutive secretion). In certain cell types, some soluble proteins are stored in secretory vesicles **7** and are released only after the cell receives an appropriate neural or hormonal signal (regulated secretion). Lysosome-destined membrane and soluble proteins, which are transported in vesicles that bud from the *trans*-Golgi **8**, first move to the late endosome and then to the lysosome. *Endocytic pathway:* Membrane and soluble extracellular proteins taken up in vesicles that bud from the plasma membrane **9** also can move to the lysosome via the endosome.

that collect “cargo” proteins in buds arising from the membrane of one compartment and then deliver these cargo proteins to the next compartment by fusing with the membrane of that compartment. Importantly, as transport vesicles bud from one membrane and fuse with the next, the same face of the membrane remains oriented toward the cytosol. Therefore once a protein has been inserted into the membrane or the lumen of the ER, the protein can be carried along the secretory pathway, moving from one organelle to the next without being translocated across another membrane or altering its orientation within the membrane. Similarly, the endocytic pathway uses vesicle traffic to transport proteins from the plasma membrane to the endosome and lysosome and thus preserves their orientation in the membrane of these organelles. Figure 14-1 outlines the main secretory and endocytic pathways in the cell.

Reduced to its simplest elements, the secretory pathway operates in two stages. The first stage takes place in the rough endoplasmic reticulum (ER) (Figure 14-1, step 1). As described in Chapter 13, newly synthesized soluble and membrane proteins are translocated into the ER, where they fold into their proper conformation and receive covalent modifications such as N-linked and O-linked carbohydrates and disulfide bonds. Once newly synthesized proteins are properly folded and have received their correct modifications in the ER lumen, they progress to the second stage of the secretory pathway, transport to and through the Golgi.

The second stage of the secretory pathway can be summarized as follows. In the ER, cargo proteins are packaged into anterograde (forward-moving) transport vesicles (Figure 14-1, step 2). These vesicles fuse with each other to form a flattened membrane-bounded compartment known as the *cis*-Golgi network or *cis*-Golgi cisterna (a “cistern” is a container for holding water or other liquid). Certain proteins, mainly proteins that function in the ER, can be retrieved from the *cis*-Golgi cisterna to the ER via a different set of retrograde (backward-moving) transport vesicles (step 3). In a manner reminiscent of an assembly line, the new *cis*-Golgi cisterna with its cargo of proteins physically moves from the *cis* position (nearest the ER) to the *trans* position (farthest from the ER), successively becoming first a *medial*-Golgi cisterna and then a *trans*-Golgi cisterna (step 4). This process, known as *cisternal maturation*, primarily involves retrograde transport vesicles (step 5), which retrieve enzymes and other Golgi-resident proteins from later to earlier Golgi cisternae, thereby “maturing” the *cis*-Golgi to the *medial*-Golgi, and the *medial*-Golgi to the *trans*-Golgi. As secretory proteins move through the Golgi, they can receive further modifications to linked carbohydrates by specific glycosyl transferases that are housed in the different Golgi compartments.

Proteins in the secretory pathway are eventually delivered to a complex network of membranes and vesicles termed the *trans*-Golgi network (TGN). The TGN is a major branch point in the secretory pathway. It is at this point that proteins are loaded into different kinds of vesicles and thereby trafficked to different destinations. Depending on which kind of vesicle the protein is loaded into, it will be either transported

to the plasma membrane and secreted immediately, stored for later release, or shipped to the lysosome (steps 6–8). The process by which a vesicle moves to and fuses with the plasma membrane and releases its contents is known as **exocytosis**. In all cell types, at least some proteins are secreted continuously, while others are stored inside the cell until a signal for exocytosis causes them to be released. Secretory proteins destined for lysosomes are first transported by vesicles from the *trans*-Golgi network to a compartment usually called the **late endosome**; proteins then are transferred to the lysosome by direct fusion of the endosome with the lysosomal membrane.

Endocytosis is related mechanistically to the secretory pathway. In the endocytic pathway, vesicles bud inward from the plasma membrane, bringing membrane proteins and their bound ligands into the cell (see Figure 14-1, right). After being internalized by endocytosis, some proteins are transported to lysosomes via the late endosome, whereas others are recycled back to the cell surface.

In this chapter we first discuss the experimental techniques that have contributed to our knowledge of the secretory pathway and endocytosis. Then we focus on the general mechanisms of membrane budding and fusion. We will see that although different kinds of transport vesicles utilize distinct sets of proteins for their formation and fusion, all vesicles use the same general mechanism for budding, selection of particular sets of cargo molecules, and fusion with the appropriate target membrane. In the remaining sections of the chapter, we discuss both the early and late stages of the secretory pathway, including how specificity of targeting to different destinations is achieved, and conclude with a discussion of how proteins are transported to the lysosome by the endocytic pathway.

14.1 Techniques for Studying the Secretory Pathway

The key to understanding how proteins are transported through the organelles of the secretory pathway has been to develop a basic description of the function of transport vesicles. Many components required for the formation and fusion of transport vesicles have been identified in the past decade by a remarkable convergence of the genetic and biochemical approaches described in this section. All studies of intracellular protein trafficking employ some method for assaying the transport of a given protein from one compartment to another. We begin by describing how intracellular protein transport can be followed in living cells and then consider genetic and *in vitro* systems that have proved useful in elucidating the secretory pathway.

Transport of a Protein Through the Secretory Pathway Can Be Assayed in Living Cells

The classic studies of G. Palade and his colleagues in the 1960s first established the order in which proteins move from one organelle to the next in the secretory pathway.

These early studies also showed that secretory proteins are never released into the cytosol, the first indication that transported proteins are always associated with some type of membrane-bounded intermediate. In these experiments, which combined pulse-chase labeling (see Figure 3-40) and autoradiography, radioactively labeled amino acids were injected into the pancreas of hamsters. At different times after injection, the animals were sacrificed and the pancreatic cells were immediately fixed with glutaraldehyde, sectioned, and subjected to autoradiography to visualize the location of the radiolabeled proteins. Because the radioactive amino acids were administered in a short pulse, only those proteins synthesized immediately after injection were labeled, forming a distinct cohort of labeled proteins whose transport could be followed. In addition, because pancreatic acinar cells are dedicated secretory cells, almost all of the labeled amino acids in these cells are incorporated into secretory proteins, facilitating the observation of transported proteins.

Although autoradiography is rarely used today to localize proteins within cells, these early experiments illustrate the two basic requirements for any assay of intercompartmental transport. First, it is necessary to label a cohort of proteins in an early compartment so that their subsequent transfer to later compartments can be followed with time. Second, it is necessary to have a way to identify the compartment in which a labeled protein resides. Here we describe two modern experimental procedures for observing the intracellular trafficking of a secretory protein in almost any type of cell.

In both procedures, a gene encoding an abundant membrane glycoprotein (G protein) from vesicular stomatitis

virus (VSV) is introduced into cultured mammalian cells either by transfection or simply by infecting the cells with the virus. The treated cells, even those that are not specialized for secretion, rapidly synthesize the VSV G protein on the ER like normal cellular secretory proteins. Use of a mutant encoding a temperature-sensitive VSV G protein allows researchers to turn subsequent transport of this protein on and off. At the restrictive temperature of 40 °C, newly made VSV G protein is misfolded and therefore retained within the ER by quality-control mechanisms discussed in Chapter 13, whereas at the permissive temperature of 32 °C, the protein is correctly folded and is transported through the secretory pathway to the cell surface. Importantly, the misfolding of the temperature-sensitive VSV G protein is reversible; thus when cells synthesizing mutant VSV G protein are grown at 40 °C and then shifted to 32 °C, the misfolded mutant VSV G protein that had accumulated in the ER will refold and be transported normally. This clever use of a temperature-sensitive mutation in effect defines a protein cohort whose subsequent transport can be followed.

In two variations of this basic procedure, transport of VSV G protein is monitored by different techniques. Studies using both of these modern trafficking assays and Palade's early experiments all came to the same conclusion: in mammalian cells vesicle-mediated transport of a protein molecule from its site of synthesis on the rough ER to its arrival at the plasma membrane takes from 30 to 60 minutes.

Microscopy of GFP-Labeled VSV G Protein One approach for observing transport of VSV G protein employs a hybrid gene

VIDEO: Transport of VSVG-GFP Through the Secretory Pathway

EXPERIMENTAL FIGURE 14-2 Protein transport through the secretory pathway can be visualized by fluorescence microscopy of cells producing a GFP-tagged membrane protein. Cultured cells were transfected with a hybrid gene encoding the viral membrane glycoprotein VSV G protein linked to the gene for green fluorescent protein (GFP). A mutant version of the viral gene was used so that newly made hybrid protein (VSVG-GFP) was retained in the ER at 40 °C but was released for transport at 32 °C. (a) Fluorescence micrographs of cells just before and two times after they were shifted to the lower temperature. Movement of VSVG-GFP from the ER to the Golgi and

finally to the cell surface occurred within 180 minutes. The scale bar is 5 μ m. (b) Plot of the levels of VSVG-GFP in the endoplasmic reticulum (ER), Golgi, and plasma membrane (PM) at different times after shift to lower temperature. The kinetics of transport from one organelle to another can be reconstructed from computer analysis of these data. The decrease in total fluorescence that occurs at later times probably results from slow inactivation of GFP fluorescence. [From Jennifer Lippincott-Schwartz and Koret Hirschberg, Metabolism Branch, National Institute of Child Health and Human Development.]

in which the viral gene is fused to the gene encoding *green fluorescent protein (GFP)*, a naturally fluorescent protein (Chapter 9). The hybrid gene is transfected into cultured cells by techniques described in Chapter 5. When cells expressing the temperature-sensitive form of the hybrid protein (VSVG-GFP) are grown at the restrictive temperature, VSVG-GFP accumulates in the ER, which appears as a lacy network of membranes when cells are observed in a fluorescent microscope. When the cells are subsequently shifted to a permissive temperature, the VSVG-GFP can be seen to move first to the membranes of the Golgi apparatus, which are densely concentrated at the edge of the nucleus, and then to the cell surface (Figure 14-2a). By observing the distribution of VSVG-GFP at different times after shifting cells to the permissive temperature, researchers have determined how long VSVG-GFP resides in each organelle of the secretory pathway (Figure 14-2b).

Detection of Compartment-Specific Oligosaccharide Modifications A second way to follow the transport of secretory proteins takes advantage of modifications to their carbohy-

drate side chains that occur at different stages of the secretory pathway. To understand this approach, recall that many secretory proteins leaving the ER contain one or more copies of the N-linked oligosaccharide $\text{Man}_8(\text{GlcNAc})_2$, which are synthesized and attached to secretory proteins in the ER (see Figure 13-18). As a protein moves through the Golgi complex, different enzymes localized to the *cis*-, *medial*-, and *trans*-Golgi cisternae catalyze an ordered series of reactions to these core $\text{Man}_8(\text{GlcNAc})_2$ chains, as discussed in a later section of this chapter. For instance, glycosidases that reside specifically in the *cis*-Golgi compartment sequentially trim mannose residues off the core oligosaccharide to yield a “trimmed” form, $\text{Man}_5(\text{GlcNAc})_2$. Scientists can use a specialized carbohydrate-cleaving enzyme known as endoglycosidase D to distinguish glycosylated proteins that remain in the ER from those that have entered the *cis*-Golgi: trimmed *cis*-Golgi-specific oligosaccharides are cleaved from proteins by endoglycosidase D, whereas the core (untrimmed) oligosaccharide chains on secretory proteins within the ER are resistant to cleavage by this enzyme (Figure 14-3a). Because

EXPERIMENTAL FIGURE 14-3 Transport of a membrane glycoprotein from the ER to the Golgi can be assayed based on sensitivity to cleavage by endoglycosidase D. Cells expressing a temperature-sensitive VSV G protein (VSVG) were labeled with a pulse of radioactive amino acids at the nonpermissive temperature so that labeled protein was retained in the ER. At periodic times after a return to the permissive temperature of 32 °C, VSVG was extracted from cells and digested with endoglycosidase D. (a) As proteins move to the *cis*-Golgi from the ER, the core oligosaccharide $\text{Man}_8(\text{GlcNAc})_2$ is trimmed to $\text{Man}_5(\text{GlcNAc})_2$ by enzymes that reside in the *cis*-Golgi compartment. Endoglycosidase D cleaves the oligosaccharide chains from proteins processed in the *cis*-Golgi but not from proteins in the

ER. (b) SDS gel electrophoresis of the digestion mixtures resolves the resistant, uncleaved (slower-migrating) and sensitive, cleaved (faster-migrating) forms of labeled VSVG. As this electrophoretogram shows, initially all of the VSVG was resistant to digestion, but with time an increasing fraction was sensitive to digestion, reflecting protein transported from the ER to the Golgi and processed there. In control cells kept at 40 °C, only slow-moving, digestion-resistant VSVG was detected after 60 minutes (not shown). (c) Plot of the proportion of VSVG that is sensitive to digestion, derived from electrophoretic data, reveals the time course of ER → Golgi transport. [From C. J. Beckers et al., 1987, *Cell* 50:523.]

a deglycosylated protein produced by endoglycosidase D digestion moves faster on an SDS gel than the corresponding glycosylated protein, these proteins can be readily distinguished (Figure 14-3b).

This type of assay can be used to track movement of VSV G protein in virus-infected cells pulse-labeled with radioactive amino acids. Immediately after labeling, all the labeled VSV G protein is still in the ER and, upon extraction, is resistant to digestion by endoglycosidase D, but with time the fraction of the extracted glycoprotein that is sensitive to digestion increases. This conversion of VSV G protein from an endoglycosidase D-resistant form to an endoglycosidase D-sensitive form corresponds to vesicular transport of the protein from the ER to the *cis*-Golgi. Note that transport of VSV G protein from the ER to the Golgi takes about 30 minutes as measured by either the assay based on oligosaccharide processing or fluorescence microscopy of VSVG-GFP (Figure 14-3c). A variety of assays based on specific carbohydrate modifications that occur in later Golgi compartments have been developed to measure progression of VSV G protein through each stage of the Golgi apparatus.

Yeast Mutants Define Major Stages and Many Components in Vesicular Transport

The general organization of the secretory pathway and many of the molecular components required for vesicle trafficking are similar in all eukaryotic cells. Because of this conservation, genetic studies with yeast have been useful in confirming the sequence of steps in the secretory pathway and in identifying many of the proteins that participate in vesicular traffic. Although yeasts secrete few proteins into the growth medium, they continuously secrete a number of enzymes that remain localized in the narrow space between the plasma membrane

and the cell wall. The best studied of these, invertase, hydrolyzes the disaccharide sucrose to glucose and fructose.

A large number of yeast mutants initially were identified based on their ability to secrete proteins at one temperature and inability to do so at a higher, nonpermissive temperature. When these temperature-sensitive *secretion (sec)* mutants are transferred from the lower to the higher temperature, they accumulate secretory proteins at the point in the pathway blocked by the mutation. Analysis of such mutants identified five classes (A–E) characterized by protein accumulation in the cytosol, rough ER, small vesicles taking proteins from the ER to the Golgi complex, Golgi cisternae, or constitutive secretory vesicles (Figure 14-4). Subsequent characterization of *sec* mutants in the various classes has helped elucidate the fundamental components and molecular mechanisms of vesicle trafficking that we discuss in later sections.

To determine the order of the steps in the pathway, researchers analyzed double *sec* mutants. For instance, when yeast cells contain mutations in both class B and class D functions, proteins accumulate in the rough ER, not in the Golgi cisternae. Since proteins accumulate at the earliest blocked step, this finding shows that class B mutations must act at an earlier point in the secretory pathway than class D mutations do. These studies confirmed that as a secreted protein is synthesized and processed, it moves sequentially from the cytosol → rough ER → ER-to-Golgi transport vesicles → Golgi cisternae → secretory vesicles and finally is exocytosed.

The three methods outlined in this section have delineated the major steps of the secretory pathway and have contributed to the identification of many of the proteins responsible for vesicle budding and fusion. Currently each of the individual steps in the secretory pathway is being studied in mechanistic detail, and increasingly, biochemical assays and molecular genetic studies are used to study each of these steps in terms of the function of individual protein molecules.

EXPERIMENTAL FIGURE 14-4 Phenotypes of yeast *sec* mutants identified five stages in the secretory pathway. These temperature-sensitive mutants can be grouped into five classes based on the site where newly made secretory proteins (red dots) accumulate

when cells are shifted from the permissive temperature to the higher, nonpermissive one. Analysis of double mutants permitted the sequential order of the steps to be determined. [See P. Novick et al., 1981, *Cell* 25:461, and C. A. Kaiser and R. Schekman, 1990, *Cell* 61:723.]

EXPERIMENTAL FIGURE 14-5 A cell-free assay demonstrates protein transport from one Golgi cisterna to another. (a) A mutant line of cultured fibroblasts is essential in this type of assay. In this example, the cells lack the enzyme *N*-acetylglucosamine transferase I (step 2 in Figure 14-14). In wild-type cells, this enzyme is localized to the *medial*-Golgi and modifies *N*-linked oligosaccharides by the addition of one *N*-acetylglucosamine. In VSV-infected wild-type cells, the oligosaccharide on the viral G protein is modified to a typical complex oligosaccharide, as shown in the *trans*-Golgi panel. In infected mutant cells, however, the G protein reaches the cell surface with a

simpler high-mannose oligosaccharide containing only two *N*-acetylglucosamine and five mannose residues. (b) When Golgi cisternae isolated from infected mutant cells are incubated with Golgi cisternae from normal, uninfected cells, the VSV G protein produced in vitro contains the additional *N*-acetylglucosamine. This modification is carried out by transferase enzyme that is moved by transport vesicles from the wild-type *medial*-Golgi cisternae to the mutant *cis*-Golgi cisternae in the reaction mixture. [See W. E. Balch et al., 1984, *Cell* **39**:405 and 525; W. A. Braell et al., 1984, *Cell* **39**:511; and J. E. Rothman and T. Söllner, 1997, *Science* **276**:1212.]

Cell-Free Transport Assays Allow Dissection of Individual Steps in Vesicular Transport

In vitro assays for intercompartmental transport are powerful complementary approaches to studies with yeast *sec* mutants for identifying and analyzing the cellular components responsible for vesicular trafficking. In one application of this approach, cultured mutant cells lacking one of the enzymes that modify *N*-linked oligosaccharide chains in the Golgi are infected with vesicular stomatitis virus (VSV), and the fate of the VSV G protein is followed. For example, if infected cells lack *N*-acetylglucosamine transferase I, they produce abundant amounts of VSV G protein but cannot add *N*-acetylglucosamine residues to the oligosaccharide chains in the *medial*-Golgi as wild-type cells do (Figure 14-5a). When Golgi membranes isolated from such mutant cells are mixed with Golgi membranes from wild-type, uninfected cells, the addition of *N*-acetylglucosamine to VSV G protein is restored (Figure 14-5b). This modification is the consequence of vesicular transport of *N*-acetylglucosamine transferase I from the wild-type *medial*-Golgi to the *cis*-Golgi isolated from virally infected mutant cells. Successful intercompartmental transport in this cell-free system depends on requirements that are typical of a normal physiological process, including a cytosolic extract, a source of chemical energy in the form of ATP and GTP, and incubation at physiological temperatures.

In addition, under appropriate conditions a uniform population of the transport vesicles that move *N*-acetylglucosamine

transferase I from the *medial*- to *cis*-Golgi can be purified away from the donor wild-type Golgi membranes by centrifugation. By examining the proteins that are enriched in these vesicles, scientists have been able to identify many of the integral membrane proteins and peripheral vesicle coat proteins that are the structural components of this type of vesicle. Moreover, fractionation of the cytosolic extract required for transport in cell-free reaction mixtures has permitted isolation of the various proteins required for formation of transport vesicles and of proteins required for the targeting and fusion of vesicles with appropriate acceptor membranes. In vitro assays similar in general design to the one shown in Figure 14-5 have been used to study various transport steps in the secretory pathway.

KEY CONCEPTS of Section 14.1

Techniques for Studying the Secretory Pathway

- All assays for following the trafficking of proteins through the secretory pathway in living cells require a way to label a cohort of secretory proteins and a way to identify the compartments where labeled proteins subsequently are located.
- Pulse labeling with radioactive amino acids can specifically label a cohort of newly made proteins in the ER. Alternatively,

a temperature-sensitive mutant protein that is retained in the ER due to misfolding at the nonpermissive temperature will be released as a cohort for transport when cells are shifted to the permissive temperature.

- Transport of a fluorescently labeled protein along the secretory pathway can be observed by microscopy (see Figure 14-2). Transport of a radiolabeled protein commonly is tracked by following compartment-specific covalent modifications to the protein.
- Many of the components required for intracellular protein trafficking have been identified in yeast by analysis of temperature-sensitive *sec* mutants defective for the secretion of proteins at the nonpermissive temperature (see Figure 14-4).
- Cell-free assays for intercompartmental protein transport have allowed the biochemical dissection of individual steps of the secretory pathway. Such *in vitro* reactions can be used to produce pure transport vesicles and to test the biochemical function of individual transport proteins.

14.2 Molecular Mechanisms of Vesicle Budding and Fusion

Small membrane-bounded vesicles that transport proteins from one organelle to another are common elements in the secretory and endocytic pathways (see Figure 14-1). These vesicles bud from the membrane of a particular “parent” (*donor*) organelle and fuse with the membrane of a particular “target” (*destination*) organelle. Although each step in the secretory and endocytic pathways employs a different type of vesicle, studies employing genetic and biochemical techniques have revealed that each of the different vesicular transport steps is simply a variation on a common theme. In this section we explore the basic mechanisms underlying vesicle budding and fusion that all vesicle types have in common, before discussing the details unique to each pathway.

Assembly of a Protein Coat Drives Vesicle Formation and Selection of Cargo Molecules

The budding of vesicles from their parent membrane is driven by the polymerization of soluble protein complexes onto the membrane to form a proteinaceous vesicle coat (Figure 14-6a). Interactions between the cytosolic portions of integral membrane proteins and the vesicle coat gather the appropriate cargo proteins into the forming vesicle. Thus the coat gives curvature to the membrane to form a vesicle and acts as the filter to determine which proteins are admitted into the vesicle.

The coat is also responsible for including in the vesicle fusion proteins known as v-SNAREs. After formation of a vesicle is completed, the coat is shed, exposing the vesicle’s v-SNARE proteins. The specific joining of v-SNAREs in the vesicle membrane with cognate t-SNAREs in the target membrane to which the vesicle is docked brings the membranes into close apposition, allowing the two bilayers to

FIGURE 14-6 Overview of vesicle budding and fusion with a target membrane. (a) Budding is initiated by recruitment of a small GTP-binding protein to a patch of donor membrane. Complexes of coat proteins in the cytosol then bind to the cytosolic domain of membrane cargo proteins, some of which also act as receptors that bind soluble proteins in the lumen, thereby recruiting luminal cargo proteins into the budding vesicle. (b) After being released and shedding its coat, a vesicle fuses with its target membrane in a process that involves interaction of cognate SNARE proteins.

fuse (Figure 14-6b). Regardless of target organelle, all transport vesicles use v-SNAREs and t-SNAREs to bud and fuse.

Three major types of coated vesicles have been characterized, each with a different type of protein coat and each formed by reversible polymerization of a distinct set of protein subunits (Table 14-1). Each type of vesicle, named for its primary coat proteins, transports cargo proteins from particular parent organelles to particular destination organelles:

- **COPII** vesicles transport proteins from the ER to the Golgi.
- **COPI** vesicles mainly transport proteins in the retrograde direction between Golgi cisternae and from the *cis*-Golgi back to the ER.
- **Clathrin** vesicles transport proteins from the plasma membrane (cell surface) and the *trans*-Golgi network to late endosomes.

TABLE 14-1 Coated Vesicles Involved in Protein Trafficking

Vesicle Type	Transport Step Mediated	Coat Proteins	Associated GTPase
COPII	ER to <i>cis</i> -Golgi	Sec23/Sec24 and Sec13/Sec31 complexes, Sec16	Sar1
COPI	<i>cis</i> -Golgi to ER Later to earlier Golgi cisternae	Coatomers containing seven different COP subunits	ARF
Clathrin and adapter proteins*	<i>trans</i> -Golgi to endosome	Clathrin + AP1 complexes	ARF
	<i>trans</i> -Golgi to endosome	Clathrin + GGA	ARF
	Plasma membrane to endosome	Clathrin + AP2 complexes	ARF
	Golgi to lysosome, melanosome, or platelet vesicles	AP3 complexes	ARF

*Each type of AP complex consists of four different subunits. It is not known whether the coat of AP3 vesicles contains clathrin.

Every vesicle-mediated trafficking step is thought to utilize some kind of vesicle coat; however, a specific coat protein complex has not been identified for every type of vesicle. For example, vesicles that move proteins from the *trans*-Golgi to the plasma membrane during either constitutive or regulated secretion exhibit a uniform size and morphology suggesting that their formation is driven by assembly of a regular coat structure, yet researchers have not identified specific coat proteins surrounding these vesicles.

The general scheme of vesicle budding shown in Figure 14-6a applies to all three known types of coated vesicles. Experiments with isolated or artificial membranes and purified coat proteins have shown that polymerization of the coat proteins onto the cytosolic face of the parent membrane is necessary to produce the high curvature of the membrane that is typical of a transport vesicle about 50 nm in diameter. Electron micrographs of *in vitro* budding reactions often reveal structures that exhibit discrete regions of the parent membrane bearing a dense coat accompanied by the curvature characteristic of a completed vesicle (Figure 14-7). Such structures, usually called *vesicle buds*, appear to be intermediates that are visible after the coat has begun to polymerize but before the completed vesicle pinches off from the parent

membrane. The polymerized coat proteins are thought to form a curved lattice that drives the formation of a vesicle bud by adhering to the cytosolic face of the membrane.

A Conserved Set of GTPase Switch Proteins Controls Assembly of Different Vesicle Coats

Based on *in vitro* vesicle-budding reactions with isolated membranes and purified coat proteins, scientists have determined the minimum set of coat components required to form each of the three major types of vesicles. Although most of the coat proteins differ considerably from one type of vesicle to another, the coats of all three vesicles contain a small GTP-binding protein that acts as a regulatory subunit to control coat assembly (see Figure 14-6a). For both COPI and clathrin vesicles, this GTP-binding protein is known as *ARF protein*. A different but related GTP-binding protein known as *Sar1 protein* is present in the coat of COPII vesicles. Both ARF and Sar1 are monomeric proteins with an overall structure similar to that of Ras, a key intracellular signal-transducing protein (see Figure 16-19). ARF and Sar1 proteins, like Ras, belong to the **GTPase superfamily** of switch proteins that cycle between GDP-bound and GTP-bound forms (see Figure 3-32 to review the mechanism of GTPase “switch” proteins).

The cycle of GTP binding and hydrolysis by ARF and Sar1 are thought to control the initiation of coat assembly,

EXPERIMENTAL FIGURE 14-7 Vesicle buds can be visualized during *in vitro* budding reactions. When purified COPII coat components are incubated with isolated ER vesicles or artificial phospholipid vesicles (liposomes), polymerization of the coat proteins on the vesicle surface induces emergence of highly curved buds. In this electron micrograph of an *in vitro* budding reaction, note the distinct membrane coat, visible as a dark protein layer, present on the vesicle buds. [From K. Matsuoka et al., 1988, *Cell* 93(2):263.]

FIGURE 14-8 Model for the role of Sar1 in the assembly and disassembly of COPII coats. Step **1**: Interaction of soluble GDP-bound Sar1 with the exchange factor Sec12, an ER integral membrane protein, catalyzes exchange of GTP for GDP on Sar1. In the GTP-bound form of Sar1, its hydrophobic N-terminus extends outward from the protein's surface and anchors Sar1 to the ER membrane. Step **2**: Sar1 attached to the membrane serves as a binding site for the Sec23/Sec24 coat protein complex. Membrane cargo proteins are recruited to the forming vesicle bud by binding of specific short sequences (sorting signals) in their cytosolic regions to sites on the Sec23/Sec24 complex. Some membrane cargo proteins also act as receptors that bind soluble proteins in the lumen. The coat is completed by assembly of a second type of coat complex composed of Sec13 and Sec31 (not shown). Step **3**: After the vesicle coat is complete, the Sec23 coat subunit promotes GTP hydrolysis by Sar1. Step **4**: Release of Sar1-GDP from the vesicle membrane causes disassembly of the coat. [See S. Springer et al., 1999, *Cell* **97**:145.]

as schematically depicted for the assembly of COPII vesicles in Figure 14-8. First, an ER membrane protein known as Sec12 catalyzes release of GDP from cytosolic Sar1-GDP and binding of GTP. This *guanine nucleotide-exchange factor* apparently receives and integrates multiple as-yet-unknown signals, probably including the presence in the ER membrane of cargo proteins that are ready to be transported. Binding of GTP causes a conformational change in Sar1 that exposes its hydrophobic N-terminus, which then becomes embedded in the phospholipid bilayer and tethers Sar1-GTP to the ER membrane (Figure 14-8, step **1**). The membrane-attached Sar1-GTP drives polymerization of cytosolic complexes of COPII subunits on the membrane, eventually leading to formation of vesicle buds (step **2**). Once COPII vesicles are released from the donor membrane, the Sar1 GTPase activity hydrolyzes Sar1-GTP in the vesicle membrane to Sar1-GDP with the assistance of one of the coat subunits (step **3**). This hydrolysis triggers disassembly of the COPII coat (step **4**). Thus Sar1 couples a cycle of GTP binding and hydrolysis to the formation and then dissociation of the COPII coat.

ARF protein undergoes a similar cycle of nucleotide exchange and hydrolysis coupled to the assembly of vesicle coats composed either of COPI or of clathrin and other coat proteins (AP complexes), discussed later. A covalent protein modification known as a myristate anchor on the N-terminus of ARF protein weakly tethers ARF-GDP to the Golgi membrane. When GTP is exchanged for the bound GDP by a nucleotide-exchange factor attached to the Golgi membrane, the resulting conformational change in ARF allows hydrophobic residues in its N-terminal segment to insert into the membrane bilayer. The resulting tight association of ARF-GTP with the membrane serves as the foundation for further coat assembly.

Drawing on the structural similarities of Sar1 and ARF to other small GTPase switch proteins, researchers have constructed genes encoding mutant versions of the two proteins that have predictable effects on vesicular traffic when transfected into cultured cells. For example, in cells expressing mutant versions of Sar1 or ARF that cannot hydrolyze GTP, vesicle coats form and vesicle buds pinch off. However, because the mutant proteins cannot trigger disassembly of the coat, all available coat subunits eventually become permanently assembled into coated vesicles that are unable to fuse with target membranes. Addition of a nonhydrolyzable GTP analog to *in vitro* vesicle-budding reactions causes a similar blocking of coat disassembly. The vesicles that form in such reactions have coats that never dissociate, allowing their composition and structure to be more readily analyzed. The purified COPI vesicles shown in Figure 14-9 were produced in such a budding reaction.

Targeting Sequences on Cargo Proteins Make Specific Molecular Contacts with Coat Proteins

In order for transport vesicles to move specific proteins from one compartment to the next, vesicle buds must be able to discriminate among potential membrane and soluble cargo proteins, accepting only those cargo proteins that should

EXPERIMENTAL FIGURE 14-9 Coated vesicles accumulate during *in vitro* budding reactions in the presence of a nonhydrolyzable analog of GTP. When isolated Golgi membranes are incubated with a cytosolic extract containing COPI coat proteins, vesicles form and bud off from the membranes. Inclusion of a nonhydrolyzable analog of GTP in the budding reaction prevents disassembly of the coat after vesicle release. This micrograph shows COPI vesicles generated in such a reaction and separated from membranes by centrifugation. Coated vesicles prepared in this way can be analyzed to determine their components and properties. [Courtesy of L. Orci.]

advance to the next compartment and excluding those that should remain as residents in the donor compartment. In addition to sculpting the curvature of a donor membrane, the vesicle coat functions in selecting specific proteins as cargo. The primary mechanism by which the vesicle coat selects cargo molecules is by directly binding to specific sequences, or **sorting signals**, in the cytosolic portion of membrane cargo

proteins (see Figure 14-6a). The polymerized coat thus acts as an affinity matrix to cluster selected membrane cargo proteins into forming vesicle buds. Since soluble proteins within the lumen of parent organelles cannot contact the coat directly, they require a different kind of sorting signal. Soluble luminal proteins often contain what can be thought of as *luminal sorting signals*, which bind to the luminal domains of certain membrane cargo proteins that act as receptors for luminal cargo proteins. The properties of several known sorting signals in membrane and soluble proteins are summarized in Table 14-2. We describe the role of these signals in more detail in later sections.

TABLE 14-2 Known Sorting Signals That Direct Proteins to Specific Transport Vesicles

Signal Sequence*	Proteins with Signal	Signal Receptor	Vesicles That Incorporate Signal-Bearing Protein
LUMINAL SORTING SIGNALS			
Lys-Asp-Glu-Leu (KDEL)	ER-resident soluble proteins	KDEL receptor in <i>cis</i> -Golgi membrane	COPI
Mannose 6-phosphate (M6P)	Soluble lysosomal enzymes after processing in <i>cis</i> -Golgi	M6P receptor in <i>trans</i> -Golgi membrane	Clathrin/AP1
	Secreted lysosomal enzymes	M6P receptor in plasma membrane	Clathrin/AP2
CYTOPLASMIC SORTING SIGNALS			
Lys-Lys-X-X (KKXX)	ER-resident membrane proteins	COPI α and β subunits	COPI
Di-arginine (X-Arg-Arg-X)	ER-resident membrane proteins	COPI α and β subunits	COPI
Di-acidic (e.g., Asp-X-Glu)	Cargo membrane proteins in ER	COPII Sec24 subunit	COPII
Asn-Pro-X-Tyr (NPXY)	LDL receptor in plasma membrane	AP2 complex	Clathrin/AP2
Tyr-X-X- Φ (YXX Φ)	Membrane proteins in <i>trans</i> -Golgi	AP1 (μ 1 subunit)	Clathrin/AP1
	Plasma membrane proteins	AP2 (μ 2 subunit)	Clathrin/AP2
Leu-Leu (LL)	Plasma membrane proteins	AP2 complexes	Clathrin/AP2

*X = any amino acid; Φ = hydrophobic amino acid. Single-letter amino acid abbreviations are in parentheses.

(b) SNARE complex

FIGURE 14-10 Model for docking and fusion of transport vesicles with their target membranes.

(a) The proteins shown in this example participate in fusion of secretory vesicles with the plasma membrane, but similar proteins mediate all vesicle-fusion events. **Step 1:** A Rab protein tethered via a lipid anchor to a secretory vesicle binds to an effector protein complex on the plasma membrane, thereby docking the transport vesicle on the appropriate target membrane. **Step 2:** A v-SNARE protein (in this case, VAMP) interacts with the cytosolic domains of the cognate t-SNAREs (in this case, syntaxin and SNAP-25). The very stable coiled-coil SNARE complexes that are formed hold the vesicle close to the target membrane. **Step 3:** Fusion of the two membranes immediately follows formation of SNARE complexes, but precisely how this occurs is not known. **Step 4:** Following membrane fusion, NSF in conjunction with α -SNAP protein binds to the SNARE complexes. The NSF-catalyzed hydrolysis of ATP then drives dissociation of the SNARE complexes, freeing the SNARE proteins for another round of vesicle fusion. Also at this time, Rab-GTP is hydrolyzed to Rab-GDP and dissociates from the Rab effector (not shown). (b) The SNARE complex. Numerous noncovalent interactions between four long α helices, two from SNAP-25 and one each from syntaxin and VAMP, stabilize the coiled-coil structure. [See J. E. Rothman and T. Söllner, 1997, *Science* **276**:1212, and W. Weis and R. Scheller, 1998, *Nature* **395**:328. Part (b) from Y. A. Chen and R. H. Scheller, 2001, *Nat. Rev. Mol. Cell Biol.* **2**(2):98.]

change in Rab that enables it to interact with a surface protein on a particular transport vesicle and insert its isoprenoid anchor into the vesicle membrane. Once Rab-GTP is tethered to the vesicle surface, it is thought to interact with one of a number of different large proteins, known as Rab effectors, attached to the target membrane. Binding of Rab-GTP to a Rab effector docks the vesicle on an appropriate target membrane (Figure 14-10, step 1). After vesicle fusion occurs, the GTP bound to the Rab protein is hydrolyzed to GDP, triggering the release of Rab-GDP, which then can undergo another cycle of GDP-GTP exchange, binding, and hydrolysis.

Several lines of evidence support the involvement of specific Rab proteins in vesicle-fusion events. For instance, the yeast *SEC4* gene encodes a Rab protein, and yeast cells expressing mutant Sec4 proteins accumulate secretory vesicles that are unable to fuse with the plasma membrane (class E mutants in Figure 14-4). In mammalian cells, Rab5 protein is localized to endocytic vesicles, also known as early endosomes. These uncoated vesicles form from clathrin-coated vesicles just after they bud from the plasma membrane during endocytosis (see Figure 14-1, step 9). The fusion of early endosomes with each other in cell-free systems requires the presence of Rab5, and addition of Rab5 and GTP to cell-free extracts accelerates the rate at which these vesicles fuse with

Rab GTPases Control Docking of Vesicles on Target Membranes

A second set of small GTP-binding proteins, known as *Rab* proteins, participate in the targeting of vesicles to the appropriate target membrane. Like Sar1 and ARF, Rab proteins belong to the GTPase superfamily of switch proteins. Rab proteins also contain an isoprenoid anchor that allows them to become tethered to the vesicle membrane. Conversion of cytosolic Rab-GDP to Rab-GTP, catalyzed by a specific guanine nucleotide-exchange factor, induces a conformational

each other. A long coiled protein known as EEA1 (*early endosome antigen 1*), which resides on the membrane of the early endosome, functions as the effector for Rab5. In this case, Rab5-GTP on one endocytic vesicle is thought to specifically bind to EEA1 on the membrane of another endocytic vesicle, setting the stage for fusion of the two vesicles.

A different type of Rab effector appears to function for each vesicle type and at each step of the secretory pathway. Many questions remain about how Rab proteins are targeted to the correct membrane and how specific complexes form between the different Rab proteins and their corresponding effector proteins.

Paired Sets of SNARE Proteins Mediate Fusion of Vesicles with Target Membranes

As noted previously, shortly after a vesicle buds off from the donor membrane, the vesicle coat disassembles to uncover a vesicle-specific membrane protein, a v-SNARE (see Figure 14-6b). Likewise, each type of target membrane in a cell contains t-SNARE membrane proteins, which specifically interact with v-SNAREs. After Rab-mediated docking of a vesicle on its target (destination) membrane, the interaction of cognate SNAREs brings the two membranes close enough together that they can fuse.

One of the best-understood examples of SNARE-mediated fusion occurs during exocytosis of secreted proteins (see Figure 14-10, steps 2 and 3). In this case, the v-SNARE, known as VAMP (*vesicle-associated membrane protein*), is incorporated into secretory vesicles as they bud from the *trans*-Golgi network. The t-SNAREs are *syntaxin*, an integral membrane protein in the plasma membrane, and SNAP-25, which is attached to the plasma membrane by a hydrophobic lipid anchor in the middle of the protein. The cytosolic region in each of these three SNARE proteins contains a repeating heptad sequence that allows four α helices—one from VAMP, one from syntaxin, and two from SNAP-25—to coil around one another to form a four-helix bundle (Figure 14-10b). The unusual stability of this bundled SNARE complex is conferred by the arrangement of hydrophobic and charged amino residues in the heptad repeats. The hydrophobic amino acids are buried in the central core of the bundle, and amino acids of opposite charge are aligned to form favorable electrostatic interactions between helices. As the four-helix bundles form, the vesicle and target membranes are drawn into close apposition by the embedded transmembrane domains of VAMP and syntaxin.

In vitro experiments have shown that when liposomes containing purified VAMP are incubated with other liposomes containing syntaxin and SNAP-25, the two classes of membranes fuse, albeit slowly. This finding is strong evidence that the close apposition of membranes resulting from formation of SNARE complexes is sufficient to bring about membrane fusion. Fusion of a vesicle and target membrane occurs more rapidly and efficiently in the cell than it does in liposome experiments in which fusion is catalyzed only by SNARE

proteins. The likely explanation for this difference is that in the cell, other proteins such as Rab proteins and their effectors are involved in targeting vesicles to the correct membrane.

Yeast cells, like all eukaryotic cells, express more than 20 different related v-SNARE and t-SNARE proteins. Analyses of yeast mutants defective in each of the SNARE genes have identified specific membrane-fusion events in which each SNARE protein participates. For all fusion events that have been examined, the SNAREs form four-helix bundled complexes, similar to the VAMP/syntaxin/SNAP-25 complexes that mediate fusion of secretory vesicles with the plasma membrane. However, in other fusion events (e.g., fusion of COPII vesicles with the *cis*-Golgi network), each participating SNARE protein contributes only one α helix to the bundle (unlike SNAP-25, which contributes two helices); in these cases the SNARE complexes comprise one v-SNARE and three t-SNARE molecules.

Using the in vitro liposome fusion assay, researchers have tested the ability of various combinations of individual v-SNARE and t-SNARE proteins to mediate fusion of donor and target membranes. Of the very large number of different combinations tested, only a small number could efficiently mediate membrane fusion. To a remarkable degree, the functional combinations of v-SNAREs and t-SNAREs revealed in these in vitro experiments correspond to the actual SNARE protein interactions that mediate known membrane-fusion events in the yeast cell. Thus, together with the specificity of interaction between Rab and Rab effector proteins, the specificity of the interaction between SNARE proteins can account for most, if not all, of the specificity of fusion between a particular vesicle type and its target membrane.

Dissociation of SNARE Complexes After Membrane Fusion Is Driven by ATP Hydrolysis

After a vesicle and its target membrane have fused, the SNARE complexes must dissociate to make the individual SNARE proteins available for additional fusion events. Because of the stability of SNARE complexes, which are held together by numerous noncovalent intermolecular interactions, their dissociation depends on additional proteins and the input of energy.

The first clue that dissociation of SNARE complexes required the assistance of other proteins came from in vitro transport reactions depleted of certain cytosolic proteins. The observed accumulation of vesicles in these reactions indicated that vesicles could form but were unable to fuse with a target membrane. Eventually two proteins, designated NSF and α -SNAP, were found to be required for ongoing vesicle fusion in the in vitro transport reaction. The function of NSF in vivo can be blocked selectively by *N*-ethylmaleimide (NEM), a chemical that reacts with an essential -SH group on NSF (hence the name, NEM-sensitive factor).

Yeast mutants have also contributed to our understanding of SNARE function. Among the class C yeast *sec* mutants

are strains that lack functional Sec18 or Sec17, the yeast counterparts of mammalian NSF and α -SNAP, respectively. When these class C mutants are placed at the nonpermissive temperature, they accumulate ER-to-Golgi transport vesicles; when the cells are shifted to the lower, permissive temperature, the accumulated vesicles are able to fuse with the *cis*-Golgi.

Subsequent to the initial biochemical and genetic studies identifying NSF and α -SNAP, more sophisticated *in vitro* transport assays were developed. Using these newer assays, researchers have shown that NSF and α -SNAP proteins are not necessary for actual membrane fusion but rather are required for regeneration of free SNARE proteins. NSF, a hexamer of identical subunits, associates with a SNARE complex with the aid of α -SNAP (soluble NSF attachment protein). The bound NSF then hydrolyzes ATP, releasing sufficient energy to dissociate the SNARE complex (Figure 14-10, step 4). Evidently, the defects in vesicle fusion observed in the earlier *in vitro* fusion assays and in the yeast mutants after a loss of Sec17 or Sec18 were a consequence of free SNARE proteins rapidly becoming sequestered in undissociated SNARE complexes and thus being unavailable to mediate membrane fusion.

KEY CONCEPTS of Section 14.2

Molecular Mechanisms of Vesicle Budding and Fusion

- The three well-characterized transport vesicles—COPI, COPII, and clathrin vesicles—are distinguished by the proteins that form their coats and the transport routes they mediate (see Table 14-1).
- All types of coated vesicles are formed by polymerization of cytosolic coat proteins onto a donor (parent) membrane to form vesicle buds that eventually pinch off from the membrane to release a complete vesicle. Shortly after vesicle release, the coat is shed, exposing proteins required for fusion with the target membrane (see Figure 14-6).
- Small GTP-binding proteins (ARF or Sar1) belonging to the GTPase superfamily control polymerization of coat proteins, the initial step in vesicle budding (see Figure 14-8). After vesicles are released from the donor membrane, hydrolysis of GTP bound to ARF or Sar1 triggers disassembly of the vesicle coats.
- Specific sorting signals in membrane and luminal proteins of donor organelles interact with coat proteins during vesicle budding, thereby recruiting cargo proteins to vesicles (see Table 14-2).
- A second set of GTP-binding proteins, the Rab proteins, regulate docking of vesicles with the correct target membrane. Each Rab appears to bind to a specific Rab effector associated with the target membrane.
- Each v-SNARE in a vesicular membrane specifically binds to a complex of cognate t-SNARE proteins in the target

membrane, inducing fusion of the two membranes. After fusion is completed, the SNARE complex is disassembled in an ATP-dependent reaction mediated by other cytosolic proteins (see Figure 14-10).

14.3 Early Stages of the Secretory Pathway

In this section we take a closer look at vesicular traffic between the ER and the Golgi and some of the evidence supporting the general mechanisms discussed in the previous section. Recall that *anterograde transport* from the ER to Golgi, the first vesicle trafficking step in the secretory pathway, is mediated by COPII vesicles. These vesicles contain newly synthesized proteins destined for the Golgi, cell surface, or lysosomes as well as vesicle components such as v-SNAREs that are required to target vesicles to the *cis*-Golgi membrane. Proper sorting of proteins between the ER and Golgi also requires *retrograde (reverse) transport* from the *cis*-Golgi to the ER, which is mediated by COPI vesicles (Figure 14-11). This retrograde vesicle transport serves to retrieve v-SNARE proteins and the membrane itself back to the ER to provide the necessary material for additional rounds of vesicle budding from the ER. COPI-mediated retrograde transport also retrieves missorted ER-resident proteins from the *cis*-Golgi to correct sorting mistakes.

We also discuss in this section the process by which proteins that have been correctly delivered to the Golgi advance through successive compartments of the Golgi, from *cis*- to *trans*-network. This process, known as cisternal maturation, involves budding and fusion of retrograde rather than anterograde transport vesicles.

COPII Vesicles Mediate Transport from the ER to the Golgi

COPII vesicles were first recognized when cell-free extracts of yeast rough ER membranes were incubated with cytosol and a nonhydrolyzable analog of GTP. The vesicles that formed from the ER membranes had a distinct coat similar to that on COPI vesicles but composed of different proteins, designated COPII proteins. Yeast cells with mutations in the genes for COPII proteins are class B *sec* mutants and accumulate proteins in the rough ER (see Figure 14-4). Analysis of such mutants has revealed a set of proteins required for formation of COPII vesicles, including the proteins which comprise the COPII vesicle coat.

As described previously, formation of COPII vesicles is triggered when Sec12, a guanine nucleotide-exchange factor in the ER membrane, catalyzes the exchange of bound GDP for GTP on cytosolic Sar1. This exchange induces binding of Sar1 to the ER membrane followed by binding of a complex of Sec23 and Sec24 proteins (see Figure 14-8). The resulting

FIGURE 14-11 Vesicle-mediated protein trafficking between the ER and *cis*-Golgi. Steps **1–3**: Forward (anterograde) transport is mediated by COPII vesicles, which are formed by polymerization of soluble COPII coat protein complexes (green) on the ER membrane. v-SNAREs (orange) and other cargo proteins (blue) in the ER membrane are incorporated into the vesicle by interacting with coat proteins. Soluble cargo proteins (magenta) are recruited by binding to appropriate receptors in the membrane of budding vesicles. Dissociation of the coat recycles free coat complexes and exposes v-SNARE proteins on the vesicle surface. After the uncoated vesicle becomes tethered to the *cis*-Golgi membrane in a Rab-mediated process, pairing between the exposed v-SNAREs and cognate t-SNAREs in the Golgi membrane allows vesicle fusion, releasing the contents into the *cis*-Golgi compartment (see Figure 14-10). Steps **4–6**: Reverse (retrograde) transport, mediated by vesicles coated with COPI proteins (purple), recycles the membrane bilayer and certain proteins, such as v-SNAREs and missorted ER-resident proteins (not shown), from the *cis*-Golgi to the ER. All SNARE proteins are shown in orange although v-SNAREs and t-SNAREs are distinct proteins.

ternary complex formed between Sar1•GTP, Sec23, and Sec24 is shown in Figure 14-12. After this complex forms on the ER membrane, a second complex comprising Sec13 and Sec31 proteins binds to complete the coat structure. Pure Sec13 and Sec31 proteins can spontaneously assemble into cage-like lattices. It is thought that Sec13 and Sec31 form the structural scaffold for COPII vesicles. Finally, a large fibrous

FIGURE 14-12 Three-dimensional structure of the ternary complex comprising the COPII coat proteins Sec23 and Sec24 and Sar1•GTP. Early in the formation of the COPII coat, Sec23 (orange)/Sec24 (green) complexes are recruited to the ER membrane by Sar1 (red) in its GTP-bound state. In order to form a stable ternary complex in solution for structural studies, the nonhydrolyzable GTP analog GppNHp is used. A cargo protein in the ER membrane can be recruited to COPII vesicles by interaction of a tripeptide di-acidic signal (purple) in the cargo's cytosolic domain with Sec24. The likely position of the COPII vesicle membrane and the transmembrane segment of the cargo protein are indicated. The N-terminal segment of Sar1 that tethers it to the membrane is not shown. [See X. Bi et al., 2002, *Nature* **419**:271; interaction with peptide courtesy of J. Goldberg.]

protein called Sec16, which is bound to the cytosolic surface of the ER, interacts with Sar1•GTP and the Sec13/31 and Sec23/24 complexes and acts to organize the other coat proteins, increasing the efficiency of coat polymerization. Similar to Sec13/31, clathrin also has this ability to self-assemble into a coat-like structure, as will be discussed in Section 14.4.

Certain integral ER membrane proteins are specifically recruited into COPII vesicles for transport to the Golgi. The cytosolic segments of many of these proteins contain a *di-acidic sorting signal* (the key residues in this sequence are Asp-X-Glu, or DXE in the one-letter code) (see Table 14-2). This sorting signal binds to the Sec24 subunit of the COPII coat and is essential for the selective export of certain membrane proteins from the ER (see Figure 14-12). Biochemical and genetic studies currently are under way to identify additional signals that help direct membrane cargo proteins into COPII vesicles. Other ongoing studies seek to determine how soluble cargo proteins are selectively loaded into COPII vesicles. Although purified COPII vesicles from yeast cells have been found to contain a membrane protein that binds the soluble α mating factor, the receptors for other soluble cargo proteins such as invertase are not yet known.

 The inherited disease cystic fibrosis is characterized by an imbalance in chloride and sodium ion transport in the epithelial cells of the lung, leading to fluid build-up and

difficulty breathing. Cystic fibrosis is caused by mutations in a protein known as CFTR, which is synthesized as an integral membrane protein in the ER and is transported to the Golgi before being transported to the plasma membranes of epithelial cells, where it functions as a chloride channel. Researchers have recently shown that the CFTR protein contains a diacidic sorting signal that binds to the Sec24 subunit of the COPII coat and is necessary for transport of the CFTR protein out of the ER. The most common CFTR mutation is a deletion of a phenylalanine at position 508 in the protein sequence (known as $\Delta F508$). This mutation prevents normal transport of CFTR to the plasma membrane by blocking its packaging into COPII vesicles budding from the ER. Although the $\Delta F508$ mutation is not in the vicinity of the diacidic sorting signal, this mutation may change the conformation of the cytosolic portion of CFTR so that the diacidic signal is unable to bind to Sec24. Interestingly, a folded CFTR with this mutation would still likely function properly as a normal chloride channel. However, it never reaches the membrane; the disease state is therefore caused by the absence of the channel rather than by a defective one. ■

The experiments described previously in which the transit of VSVG-GFP in cultured mammalian cells is followed by fluorescence microscopy (see Figure 14-2) provided insight into the intermediates in ER-to-Golgi transport. In some cells, small fluorescent vesicles containing VSVG-GFP could be seen to form from the ER, move less than 1 μm , and then fuse directly with the *cis*-Golgi. In other cells, in which the ER was located several micrometers from the Golgi complex, several ER-derived vesicles were seen to fuse with each other shortly after their formation, forming what is termed the *ER-to-Golgi intermediate compartment* or the *cis-Golgi network*. These larger structures then were transported along microtubules to the *cis*-Golgi, much in the way vesicles in nerve cells are transported from the cell body, where they are formed, down the long axon to the axon terminus (Chapter 18). Microtubules function much as “railroad tracks,” enabling these large aggregates of transport vesicles to move long distances to their *cis*-Golgi destination. At the time the ER-to-Golgi intermediate compartment is formed, some COPI vesicles bud off from it, recycling some proteins back to the ER.

COPI Vesicles Mediate Retrograde Transport Within the Golgi and from the Golgi to the ER

COPI vesicles were first discovered when isolated Golgi fractions were incubated in a solution containing cytosol and a nonhydrolyzable analog of GTP (see Figure 14-9). Subsequent analysis of these vesicles showed that the coat is formed from large cytosolic complexes, called *coatamers*, composed of seven polypeptide subunits. Yeast cells containing temperature-sensitive mutations in COPI proteins accumulate proteins in the rough ER at the nonpermissive temperature and thus are categorized as class B *sec* mutants (see Figure 14-4). Although discovery of these mutants initially

suggested that COPI vesicles mediate ER-to-Golgi transport, subsequent experiments showed that their main function is retrograde transport, both between Golgi cisternae and from the *cis*-Golgi to the rough ER (see Figure 14-11, *right*). Because COPI mutants cannot recycle key membrane proteins back to the rough ER, the ER gradually becomes depleted of ER proteins such as v-SNAREs necessary for COPII vesicle function. Eventually, vesicle formation from the rough ER grinds to a halt; secretory proteins continue to be synthesized but accumulate in the ER, the defining characteristic of class B *sec* mutants. The general ability of *sec* mutants involved in either COPI or COPII vesicle function to eventually block both anterograde and retrograde transport illustrates the fundamental interdependence of these two transport processes.

As discussed in Chapter 13, the ER contains several soluble proteins dedicated to the folding and modification of newly synthesized secretory proteins. These include the chaperone BiP and the enzyme protein disulfide isomerase, which are necessary for the ER to carry out its functions. Although such ER-resident luminal proteins are not specifically selected by COPII vesicles, their sheer abundance causes them to be continuously loaded passively into vesicles destined for the *cis*-Golgi. The transport of these soluble proteins back to the ER, mediated by COPI vesicles, prevents their eventual depletion.

Most soluble ER-resident proteins carry a Lys-Asp-Glu-Leu (KDEL in the one-letter code) sequence at their C-terminus (see Table 14-2). Several experiments demonstrated that this *KDEL sorting signal* is both necessary and sufficient to cause a protein bearing this sequence to be located in the ER. For instance, when a mutant protein disulfide isomerase lacking these four residues is synthesized in cultured fibroblasts, the protein is secreted. Moreover, if a protein that normally is secreted is altered so that it contains the KDEL signal at its C-terminus, the protein is located in the ER. The KDEL sorting signal is recognized and bound by the *KDEL receptor*, a transmembrane protein found primarily on small transport vesicles shuttling between the ER and the *cis*-Golgi and on the *cis*-Golgi reticulum. In addition, soluble ER-resident proteins that carry the KDEL signal have oligosaccharide chains with modifications that are catalyzed by enzymes found only in the *cis*-Golgi or *cis*-Golgi network; thus at some time these proteins must have left the ER and been transported at least as far as the *cis*-Golgi network. These findings indicate that the KDEL receptor acts mainly to retrieve soluble proteins containing the KDEL sorting signal that have escaped to the *cis*-Golgi network and return them to the ER (Figure 14-13). The KDEL receptor binds more tightly to its ligand at low pH, and it is thought that the receptor is able to bind KDEL peptides in the *cis*-Golgi but to release these peptides in the ER because the pH of the Golgi is slightly lower than that of the ER.

The KDEL receptor and other membrane proteins that are transported back to the ER from the Golgi contain a Lys-Lys-X-X sequence at the very end of their C-terminal segment, which faces the cytosol (see Table 14-2). This *KKXX sorting signal*, which binds to a complex of the COPI α and

FIGURE 14-13 Role of the KDEL receptor in retrieval of ER-resident luminal proteins from the Golgi. ER luminal proteins, especially those present at high levels, can be passively incorporated into COPII vesicles and transported to the Golgi (steps **1** and **2**). Many such proteins bear a C-terminal KDEL (Lys-Asp-Glu-Leu) sequence (red) that allows them to be retrieved. The KDEL receptor, located mainly in the *cis*-Golgi network and in both COPII and COPI vesicles, binds proteins bearing the KDEL sorting signal and returns them to the ER (steps **3** and **4**). This retrieval system prevents depletion of ER luminal proteins such as those needed for proper folding of newly made secretory proteins. The binding affinity of the KDEL receptor is very sensitive to pH. The small difference between the pH of the ER and that of the Golgi favors binding of KDEL-bearing proteins to the receptor in Golgi-derived vesicles and their release in the ER. [Adapted from J. Semenza et al., 1990, *Cell* **61**:1349.]

β subunits (two of the seven polypeptide subunits in the COPI coatamer), is both necessary and sufficient to incorporate membrane proteins into COPI vesicles for retrograde transport to the ER. Temperature-sensitive yeast mutants lacking COPI α or COPI β not only are unable to bind the KKXX signal but also are unable to retrieve proteins bearing this signal back to the ER, indicating that COPI vesicles mediate retrograde Golgi-to-ER transport.

A second sorting signal that will target proteins to COPI vesicles and thus will enable recycling from the Golgi to the ER is a di-arginine sequence. Unlike the KKXX sorting signal, which must be located at the cytoplasmically oriented C-terminus of a protein, the di-arginine sorting signal can reside in any segment of a membrane protein that is on the cytoplasmic face of the membrane.

The partitioning of proteins between the ER and Golgi complex is a highly dynamic process depending on both COPII (anterograde) and COPI (retrograde) vesicles, with each type of vesicle responsible for recycling the components necessary for the function of the other type of vesicle. The organization of this partitioning process raises an interesting puzzle: how do vesicles preferentially use the v-SNAREs that will specify fusion with the correct target membrane instead of the v-SNAREs that are being recycled and would have specificity for fusion with the donor membrane?

This basic question concerning correct membrane partitioning has recently been answered for COPII vesicles. After these vesicles form, the COPII coat proteins remain assembled long enough for the Sec23/Sec24 complex to interact with a specific tethering factor attached to the *cis*-Golgi membrane. Vesicle uncoating to expose the v-SNAREs is completed only after the COPII vesicle is already closely associated with the *cis*-Golgi membrane and the COPII v-SNAREs are in position to form complexes with their cognate t-SNAREs. Although COPII vesicles also carry COPI-specific v-SNARE proteins, which are being recycled back to the *cis*-Golgi, these COPI v-SNARE proteins included in COPII vesicles never have the opportunity to form SNARE complexes with cognate ER-localized t-SNARE proteins.

Anterograde Transport Through the Golgi Occurs by Cisternal Maturation

The Golgi complex is organized into three or four subcompartments, often arranged in a stacked set of flattened sacs, called cisternae. The subcompartments of the Golgi differ from one another according to the enzymes they contain. Many of the enzymes are glycosidases and glycosyltransferases that are involved in modifying N-linked or O-linked carbohydrates attached to secretory proteins as they transit the Golgi stack. On the whole, the Golgi complex operates much like an assembly line, with proteins moving in sequence through the Golgi stack, the modified carbohydrate chains in one compartment serving as the substrates for the modifying enzymes of the next compartment (see Figure 14-14 for a representative sequence of modification steps).

For many years it was thought that the Golgi complex was an essentially static set of compartments with small transport vesicles carrying secretory proteins forward, from the *cis*- to the *medial*-Golgi and from the *medial*- to the *trans*-Golgi. Indeed, electron microscopy reveals many small vesicles associated with the Golgi complex that appear to move proteins

FIGURE 14-14 Processing of N-linked oligosaccharide chains on glycoproteins within *cis*-, *medial*-, and *trans*-Golgi cisternae in vertebrate cells. The enzymes catalyzing each step are localized to the indicated compartments. After removal of three mannose residues in the *cis*-Golgi (step 1), the protein moves by cisternal maturation to the *medial*-Golgi. Here, three *N*-acetylglucosamine (GlcNAc) residues are added (steps 2 and 4), two more mannose residues are removed (step 3), and a single fucose is added (step 5). Processing is completed in the *trans*-Golgi by addition of three galactose residues (step 6) and finally by linkage of an *N*-acetylneuraminic acid residue to each of the galactose residues (step 7). Specific transferase enzymes add sugars to the oligosaccharide, one at a time, from sugar nucleotide precursors imported from the cytosol. This pathway represents the Golgi processing events for a typical mammalian glycoprotein. Variations in the structure of N-linked oligosaccharides can result from differences in processing steps in the Golgi. [See R. Kornfeld and S. Kornfeld, 1985, *Ann. Rev. Biochem.* 45:631.]

from one Golgi compartment to another (Figure 14-15). However, these vesicles are now known to mediate retrograde transport, retrieving ER or Golgi enzymes from a later compartment and transporting them to an earlier compartment in the secretory pathway. Thus the Golgi appears to have a highly dynamic organization, continually forming transport vesicles, though only in the retrograde direction. To see the effect this retrograde transport has on the organization of the Golgi, consider the net effect on the *medial*-Golgi compartment as enzymes from the *trans*-Golgi move to the *medial*-Golgi while enzymes from the *medial*-Golgi

VIDEO: 3-D Model of a Golgi Complex

EXPERIMENTAL FIGURE 14-15 Electron micrograph of the Golgi complex in an exocrine pancreatic cell reveals secretory and retrograde transport vesicles. A large secretory vesicle can be seen forming from the *trans*-Golgi network. Elements of the rough ER are on the bottom and left in this micrograph. Adjacent to the rough ER are transitional elements from which smooth protrusions appear to be budding. These buds form the small vesicles that transport secretory proteins from the rough ER to the Golgi complex. Interspersed among the Golgi cisternae are other small vesicles now known to function in retrograde, not anterograde, transport. [Courtesy G. Palade.]

EXPERIMENTAL FIGURE 14-16 Fluorescence-tagged fusion proteins demonstrate Golgi cisternal maturation in a living yeast cell. Yeast cells expressing the early Golgi protein Vrg4 fused to GFP (green fluorescence) and the late Golgi protein Sec7 fused to DsRed (red fluorescence) are imaged by time-lapse microscopy. The top series of images, taken approximately 1 minute apart, shows a collection of Golgi cisternae, which at any one time are labeled either with Vrg4 or Sec7. The bottom series of images show just one Golgi cisterna,

isolated by digital processing of the image. First only Vrg4-GFP is located in the isolated cisterna and then Sec7-DsRed alone is located in the isolated cisterna, following a brief period in which both proteins are co-localized in this compartment. This experiment is a direct demonstration of the cisternal maturation hypothesis, showing that the composition of individual cisternae follow a process of maturation characterized by loss of early Golgi proteins and gain of late Golgi proteins. [From Losev et al., 2006, *Nature* 441:1002.]

are transported to the *cis*-Golgi. As this process continues, the *medial*-Golgi acquires enzymes from the *trans*-Golgi while losing *medial*-Golgi enzymes to the *cis*-Golgi and thus progressively becomes a new *trans*-Golgi compartment. In this way, secretory cargo proteins acquire carbohydrate modification in the proper sequential order without being moved from one cisterna to another via anterograde vesicle transport.

The first evidence that the forward transport of cargo proteins from the *cis*- to the *trans*-Golgi occurs by such a progressive mechanism, called *cisternal maturation*, came from careful microscopic analysis of the synthesis of algal scales. These cell-wall glycoproteins are assembled in the *cis*-Golgi into large complexes visible in the electron microscope. Like other secretory proteins, newly made scales move from the *cis*- to the *trans*-Golgi, but they can be 20 times larger than the usual transport vesicles that bud from Golgi cisternae. Similarly, in the synthesis of collagen by fibroblasts, large aggregates of the procollagen precursor often form in the lumen of the *cis*-Golgi (see Figure 20-24). The procollagen aggregates are too large to be incorporated into small transport vesicles, and investigators could never find such aggregates in transport vesicles. These observations show that the forward movement of these and perhaps all secretory proteins from one Golgi compartment to another does *not* occur via small vesicles.

A particularly elegant demonstration of cisternal maturation in yeast takes advantage of different-colored fluorescent labels to image two different Golgi proteins simultaneously. Figure 14-16 shows how a *cis*-Golgi resident protein labeled with a green fluorescent protein and a *trans*-Golgi protein labeled with a red fluorescent protein behave in the same yeast cell. At any given moment individual Golgi cisternae appear to have a distinct compartmental identity, in the sense that

they contain either the *cis*-Golgi protein or the *trans*-Golgi protein but only rarely contain both proteins. However, over time an individual cisterna labeled with the *cis*-Golgi protein can be seen to progressively lose this protein and acquire the *trans*-Golgi protein. This behavior is exactly that predicted for the cisternal maturation model, in which the composition of an individual cisterna changes as Golgi resident proteins move from later to earlier Golgi compartments.

Although most protein traffic appears to move through the Golgi complex by a cisternal maturation mechanism, there is evidence that at least some of the COPI transport vesicles that bud from Golgi membranes contain cargo proteins (rather than Golgi enzymes) and move in an anterograde (rather than retrograde) direction.

KEY CONCEPTS of Section 14.3

Early Stages of the Secretory Pathway

- COPII vesicles transport proteins from the rough ER to the *cis*-Golgi; COPI vesicles transport proteins in the reverse direction (see Figure 14-11).
- COPII coats comprise three components: the small GTP-binding protein Sar1, a Sec23/Sec24 complex, and a Sec13/Sec31 complex.
- Components of the COPII coat bind to membrane cargo proteins containing a di-acidic or other sorting signal in their cytosolic regions (see Figure 14-12). Soluble cargo proteins probably are targeted to COPII vesicles by binding to a membrane protein receptor.

- Many soluble ER-resident proteins contain a KDEL sorting signal. Binding of this retrieval sequence to a specific receptor protein in the *cis*-Golgi membrane recruits missorted ER proteins into retrograde COPI vesicles (see Figure 14-13).
- Membrane proteins needed to form COPII vesicles can be retrieved from the *cis*-Golgi by COPI vesicles. One of the sorting signals that directs membrane proteins into COPI vesicles is a KKXX sequence, which binds to subunits of the COPI coat. A distinct di-arginine sorting signal operates by a similar mechanism.
- COPI vesicles also carry Golgi-resident proteins from later to earlier compartments in the Golgi stack.
- Soluble and membrane proteins advance through the Golgi complex by cisternal maturation, a process of anterograde transport that depends on resident Golgi enzymes moving by COPI vesicular transport in a retrograde direction.

14.4 Later Stages of the Secretory Pathway

As cargo proteins move from the *cis*- to the *trans*-Golgi by cisternal maturation, modifications to their oligosaccharide chains are carried out by Golgi-resident enzymes. The retrograde trafficking of COPI vesicles from later to earlier Golgi compart-

ments maintains sufficient levels of these carbohydrate-modifying enzymes in their functional compartments. Eventually, properly processed cargo proteins reach the *trans*-Golgi network, the most distal Golgi compartment. Here, they are sorted into one of a number of different kinds of vesicles for delivery to their final destination. In this section we discuss the different kinds of vesicles that bud from the *trans*-Golgi network, the mechanisms that segregate cargo proteins among them, and key processing events that occur late in the secretory pathway. The various types of vesicles that bud from the *trans*-Golgi are summarized in Figure 14-17.

Vesicles Coated with Clathrin and/or Adapter Proteins Mediate Transport from the *trans*-Golgi

The best-characterized vesicles that bud from the *trans*-Golgi network (TGN) have a two-layered coat: an outer layer composed of the fibrous protein clathrin and an inner layer composed of *adapter protein (AP) complexes*. Purified clathrin molecules, which have a three-limbed shape, are called *triskelions*, from the Greek for “three-legged” (Figure 14-18a). Each limb contains one clathrin heavy chain (180,000 MW) and one clathrin light chain (~35,000–40,000 MW). Triskelions polymerize to form a polygonal lattice with an intrinsic curvature (Figure 14-18b). When clathrin polymerizes on a donor membrane, it does so in association with AP complexes, which fill the space between the clathrin lattice and the membrane. Each AP complex (340,000 MW) contains one copy each of four

FIGURE 14-17 Vesicle-mediated protein trafficking from the *trans*-Golgi network. COPI (purple) vesicles mediate retrograde transport within the Golgi (1). Proteins that function in the lumen or in the membrane of the lysosome are first transported from the *trans*-Golgi network via clathrin-coated (red) vesicles (2); after uncoating, these vesicles fuse with late endosomes, which deliver their contents to the lysosome. The coat on most clathrin vesicles contains additional proteins (AP complexes) not indicated here. Some vesicles from the *trans*-Golgi carrying cargo destined for the lysosome fuse with the lysosome directly (3), bypassing the endosome. These vesicles are coated with a type of AP complex (blue); it is unknown whether these vesicles also contain clathrin. The coat proteins surrounding constitutive (4) and regulated (5) secretory vesicles are not yet characterized; these vesicles carry secreted proteins and plasma-membrane proteins from the *trans*-Golgi network to the cell surface.

VIDEO: Birth of a Clathrin Coat

FIGURE 14-18 Structure of clathrin coats. (a) A clathrin molecule, called a triskelion, is composed of three heavy and three light chains. It has an intrinsic curvature due to the bend in the heavy chains. (b) Clathrin coats were formed *in vitro* by mixing purified clathrin heavy and light chains with AP2 complexes in the absence of membranes. Cryoelectron micrographs of more than 1000 assembled hexagonal clathrin barrel particles were analyzed by digital image processing to generate an average structural representation. The processed image shows only the clathrin heavy chains in a structure composed of 36 triskelions. Three representative triskelions are highlighted in red, yellow, and green. Part of the AP2 complexes packed into the interior of the clathrin cage are also visible in this representation. [See B. Pishvaei and G. Payne, 1998, *Cell* 95:443. Part (b) from Fotin et al., 2004, *Nature* 432:573.]

different adapter subunit proteins. A specific association between the globular domain at the end of each clathrin heavy chain in a triskelion and one subunit of the AP complex both promotes the co-assembly of clathrin triskelions with AP complexes and adds to the stability of the completed vesicle coat.

By binding to the cytosolic face of membrane proteins, adapter proteins determine which cargo proteins are specifically included in (or excluded from) a budding transport vesicle. Three different AP complexes are known (AP1, AP2, AP3), each with four subunits of different, though related, proteins. Recently, a second general type of adapter protein known as GGA has been shown to contain in a single 70,000 MW polypeptide both clathrin- and cargo-binding elements similar to those found in the much larger hetero-tetrameric AP complexes. Vesicles containing each type of adapter complex (AP or GGA) have been found to mediate specific transport steps (see Table 14-1). All vesicles whose coats contain one of these complexes utilize ARF to initiate coat assembly onto the donor membrane. As discussed previously, ARF also initiates assembly of COPI coats. The additional features of the membrane or protein factors that determine which type of coat will assemble after ARF attachment are not well understood at this time.

Vesicles that bud from the *trans*-Golgi network en route to the lysosome by way of the late endosome (see Figure 14-17, step 3) have clathrin coats associated with either AP1 or GGA. Both AP1 and GGA bind to the cytosolic domain of cargo proteins in the donor membrane. Membrane proteins containing a Tyr-X-X- Φ sequence, where X is any amino acid and Φ is a bulky hydrophobic amino acid, are recruited into clathrin/AP1 vesicles budding from the *trans*-Golgi network. This YXX Φ sorting signal interacts with one of the AP1 subunits in the vesicle coat. As we discuss in the next section, vesicles with clathrin/AP2 coats, which bud from the plasma membrane during endocytosis, also can recognize the YXX Φ sorting signal. Vesicles coated with GGA proteins and clathrin bind cargo molecules with a different kind of sorting sequence. Cytosolic sorting signals that specifically bind to GGA adapter

proteins include Asp-X-Leu-Leu and Asp-Phe-Gly-X- Φ sequences (where X and Φ are defined as above).

Some vesicles that bud from the *trans*-Golgi network have coats composed of the AP3 complex. Although the AP3 complex does contain a binding site for clathrin similar to the AP1 and AP2 complexes, it is not clear whether clathrin is necessary for functioning of AP3-containing vesicles since mutant versions of AP3 that lack the clathrin binding site appear to be fully functional. AP3-coated vesicles mediate trafficking to the lysosome, but they appear to bypass the late endosome and fuse directly with the lysosomal membrane (see Figure 14-17, step 2). In certain types of cells, such AP3 vesicles mediate protein transport to specialized storage compartments related to the lysosome. For example, AP3 is required for delivery of proteins to melanosomes, which contain the black pigment melanin in skin cells, and to platelet storage vesicles in megakaryocytes, large cells that fragment into dozens of platelets. Mice with mutations in either of two different subunits of AP3 not only have abnormal skin pigmentation but also exhibit bleeding disorders. The latter occur because tears in blood vessels cannot be repaired without platelets that contain normal storage vesicles.

Dynamin Is Required for Pinching Off of Clathrin Vesicles

A fundamental step in the formation of a transport vesicle that we have not yet considered is how a vesicle bud is pinched off from the donor membrane. In the case of clathrin/AP-coated vesicles, a cytosolic protein called *dynamin* is essential for release of complete vesicles. At the later stages of bud formation, dynamin polymerizes around the neck portion and then hydrolyzes GTP. The energy derived from GTP hydrolysis is thought to drive a conformational change in dynamin that stretches the vesicle neck until the vesicle pinches off (Figure 14-19). Interestingly, COPI and COPII vesicles appear to pinch off from donor membranes without the aid of a GTPase such as

Exoplasmic face

FIGURE 14-19 Model for dynamin-mediated pinching off of clathrin/AP-coated vesicles. After a vesicle bud forms, dynamin polymerizes over the neck. By a mechanism that is not well understood, dynamin-catalyzed hydrolysis of GTP leads to release of the vesicle from the donor membrane. Note that membrane proteins in the donor membrane are incorporated into vesicles by interacting with AP complexes in the coat. [Adapted from K. Takel et al., 1995, *Nature* 374:186.]

dynamin. In vitro budding experiments suggest that dimerization of ARF proteins drives the pinching off of COPI vesicles, but the mechanism is not understood.

Incubation of cell extracts with a nonhydrolyzable derivative of GTP provides dramatic evidence for the importance of dynamin in pinching off of clathrin/AP2 vesicles during endocytosis. Such treatment leads to accumulation of clathrin-coated vesicle buds with excessively long necks that are surrounded by polymeric dynamin but do not pinch off (Figure 14-20). Likewise, cells expressing mutant forms of dynamin that cannot bind GTP do not form clathrin-coated vesicles and instead accumulate similar long-necked vesicle buds encased with polymerized dynamin.

As with COPI and COPII vesicles, clathrin/AP vesicles normally lose their coat soon after their formation. Cytosolic Hsc70, a constitutive chaperone protein found in all eukaryotic cells, is thought to use energy derived from the hydrolysis of ATP to drive depolymerization of the clathrin coat into triskelions. Uncoating not only releases triskelions for reuse in the formation of additional vesicles but also exposes v-SNAREs for use in fusion with target membranes. Conformational changes that occur when ARF switches from the GTP-bound to GDP-bound state are thought to regulate the timing of

EXPERIMENTAL FIGURE 14-20 GTP hydrolysis by dynamin is required for pinching off of clathrin-coated vesicles in cell-free extracts. A preparation of nerve terminals, which undergo extensive endocytosis, was lysed by treatment with distilled water and incubated with GTP- γ -S, a nonhydrolyzable derivative of GTP. After sectioning, the preparation was treated with gold-tagged anti-dynamin antibody and viewed in the electron microscope. This image, which shows a long-necked clathrin/AP-coated bud with polymerized dynamin lining the neck, reveals that buds can form in the absence of GTP hydrolysis, but vesicles cannot pinch off. The extensive polymerization of dynamin that occurs in the presence of GTP- γ -S probably does not occur during the normal budding process. [From K. Takel et al., 1995, *Nature* 374:186; courtesy of Pietro De Camilli.]

clathrin coat depolymerization. How the action of Hsc70 might be coupled to ARF switching is not well understood.

Mannose 6-Phosphate Residues Target Soluble Proteins to Lysosomes

As we have seen, many of the sorting signals that direct cargo protein trafficking in the secretory pathway are short amino acid sequences in the targeted protein. In contrast, the sorting signal that directs soluble lysosomal enzymes from the *trans*-Golgi network to the late endosome is a carbohydrate residue, *mannose 6-phosphate* (M6P), which is formed in the *cis*-Golgi. The addition and initial processing of one or more preformed N-linked oligosaccharide precursors in the rough ER is the same for lysosomal enzymes as for membrane and secreted proteins, yielding core Man₃(GlcNAc)₂ chains (see Figure 13-18). In the *cis*-Golgi, the N-linked oligosaccharides present on most lysosomal enzymes undergo a two-step reaction sequence that generates M6P residues (Figure 14-21). The addition of M6P residues to the oligosaccharide chains of soluble lysosomal enzymes prevents these proteins from undergoing the further processing reactions characteristic of secreted and membrane proteins (see Figure 14-14).

As shown in Figure 14-22, the segregation of M6P-bearing lysosomal enzymes from secreted and membrane proteins occurs in the *trans*-Golgi network. Here, transmembrane

FIGURE 14-21 Formation of mannose 6-phosphate (M6P) residues that target soluble enzymes to lysosomes. The M6P residues that direct proteins to lysosomes are generated in the *cis*-Golgi by two Golgi-resident enzymes. **Step 1:** An *N*-acetylglucosamine (GlcNAc) phosphotransferase transfers a phosphorylated GlcNAc group to carbon atom 6 of one or more mannose residues. Because only lysosomal enzymes contain sequences (red) that are recognized and

bound by this enzyme, phosphorylated GlcNAc groups are added specifically to lysosomal enzymes. **Step 2:** After release of a modified protein from the phosphotransferase, a phosphodiesterase removes the GlcNAc group, leaving a phosphorylated mannose residue on the lysosomal enzyme. [See A. B. Cantor et al., 1992, *J. Biol. Chem.* **267**:23349, and S. Kornfeld, 1987, *FASEB J.* **1**:462.]

mannose 6-phosphate receptors bind the M6P residues on lysosome-destined proteins very tightly and specifically. Clathrin/AP1 vesicles containing the M6P receptor and bound lysosomal enzymes then bud from the *trans*-Golgi network, lose their coats, and subsequently fuse with the late endosome by mechanisms described previously. Because M6P receptors can bind M6P at the slightly acidic pH (~6.5) of the *trans*-Golgi network but not at a pH less than 6, the bound lysosomal enzymes are released within late endosomes, which have an internal pH of 5.0–5.5. Furthermore, a phosphatase within late endosomes usually removes the phosphate from M6P residues on lysosomal enzymes, preventing any rebinding to the M6P receptor that might occur in spite of the low pH in endosomes. Vesicles budding from late endosomes recycle the M6P receptor back to the *trans*-Golgi network or, on occasion, to the cell surface. Eventually, mature late endosomes fuse with lysosomes, delivering the lysosomal enzymes to their final destination.

The sorting of soluble lysosomal enzymes in the *trans*-Golgi network (Figure 14-22, steps **1–4**) shares many of the features of trafficking between the ER and *cis*-Golgi compartments mediated by COPII and COPI vesicles. First, mannose 6-phosphate acts as a sorting signal by interacting with the luminal domain of a receptor protein in the donor membrane. Second, the membrane-embedded receptors with their bound ligands are incorporated into the appropriate vesicles—in this case, either GGA or AP1-containing clathrin vesicles—by interacting with the vesicle coat. Third, these transport vesicles fuse only with one specific organelle, here the late endosome, as the result of interactions between specific v-SNAREs and t-SNAREs. And finally, intracellular transport receptors are recycled after dissociating from their bound ligand.

Study of Lysosomal Storage Diseases Revealed Key Components of the Lysosomal Sorting Pathway

A group of genetic disorders termed *lysosomal storage diseases* are caused by the absence of one or more

lysosomal enzymes. As a result, undigested glycolipids and extracellular components that would normally be degraded by lysosomal enzymes accumulate in lysosomes as large inclusions. Patients with lysosomal storage diseases can have a variety of developmental, physiological, and neurological abnormalities depending on the type and severity of the storage defect. *I-cell disease* is a particularly severe type of lysosomal storage disease in which multiple enzymes are missing from the lysosomes. Cells from affected individuals lack the *N*-acetylglucosamine phosphotransferase that is required for formation of M6P residues on lysosomal enzymes in the *cis*-Golgi (see Figure 14-21). Biochemical comparison of lysosomal enzymes from normal individuals with those from patients with *I-cell disease* led to the initial discovery of mannose 6-phosphate as the lysosomal sorting signal. Lacking the M6P sorting signal, the lysosomal enzymes in *I-cell* patients are secreted rather than being sorted to and sequestered in lysosomes.

When fibroblasts from patients with *I-cell disease* are grown in a medium containing lysosomal enzymes bearing M6P residues, the diseased cells acquire a nearly normal intracellular content of lysosomal enzymes. This finding indicates that the plasma membrane of these cells contains M6P receptors, which can internalize extracellular phosphorylated lysosomal enzymes by receptor-mediated endocytosis. This process, used by many cell-surface receptors to bring bound proteins or particles into the cell, is discussed in detail in the next section. It is now known that even in normal cells, some M6P receptors are transported to the plasma membrane and some phosphorylated lysosomal enzymes are secreted (see Figure 14-22). The secreted enzymes can be retrieved by receptor-mediated endocytosis and directed to lysosomes. This pathway thus scavenges any lysosomal enzymes that escape the usual M6P sorting pathway.

Hepatocytes from patients with *I-cell disease* contain a normal complement of lysosomal enzymes and no inclusions, even though these cells are defective in mannose phosphorylation. This finding implies that hepatocytes (the most abundant

FIGURE 14-22 Trafficking of soluble lysosomal enzymes from the trans-Golgi network and cell surface to lysosomes. Newly synthesized lysosomal enzymes, produced in the ER, acquire mannose 6-phosphate (M6P) residues in the cis-Golgi (see Figure 14-21). For simplicity, only one phosphorylated oligosaccharide chain is depicted, although lysosomal enzymes typically have many such chains. In the trans-Golgi network, proteins that bear the M6P sorting signal interact with M6P receptors in the membrane and thereby are directed into clathrin/AP1 vesicles (step 1). The coat surrounding released vesicles is rapidly depolymerized (step 2a), and the uncoated transport vesicles fuse with late endosomes (step 3). After the phosphorylated enzymes dissociate from the M6P

receptors and are dephosphorylated, late endosomes subsequently fuse with a lysosome (step 4). Note that coat proteins and M6P receptors are recycled (steps 2a and 4a), and some receptors are delivered to the cell surface (step 5). Phosphorylated lysosomal enzymes occasionally are sorted from the trans-Golgi to the cell surface and secreted. These secreted enzymes can be retrieved by receptor-mediated endocytosis (steps 6-8), a process that closely parallels trafficking of lysosomal enzymes from the trans-Golgi network to lysosomes. [See G. Griffiths et al., 1988, *Cell* 52:329; S. Kornfeld, 1992, *Ann. Rev. Biochem.* 61:307; and G. Griffiths and J. Gruenberg, 1991, *Trends Cell Biol.* 1:5.]

type of liver cell) employ an M6P-independent pathway for sorting lysosomal enzymes. The nature of this pathway, which also may operate in other cell types, is unknown. ■

Protein Aggregation in the *trans*-Golgi May Function in Sorting Proteins to Regulated Secretory Vesicles

As noted in the chapter introduction, all eukaryotic cells continuously secrete certain proteins, a process commonly called *constitutive secretion*. Specialized secretory cells also store other proteins in vesicles and secrete them only when triggered by a specific stimulus. One example of such *regulated secretion* occurs in pancreatic β cells, which store newly made insulin in special secretory vesicles and secrete insulin in response to an elevation in blood glucose (see Figure 16-38). These and other secretory cells simultaneously utilize two different types of vesicles to move proteins from the *trans*-Golgi network to the cell surface: regulated transport vesicles, often simply called secretory vesicles, and unregulated transport vesicles, also called constitutive secretory vesicles.

A common mechanism appears to sort regulated proteins as diverse as ACTH (adrenocorticotropic hormone), insulin, and trypsinogen into regulated secretory vesicles. Evidence for a common mechanism comes from experiments in which recombinant DNA techniques are used to induce the synthesis of insulin and trypsinogen in pituitary tumor cells already synthesizing ACTH. In these cells, which do not normally express insulin or trypsinogen, all three proteins segregate into the same regulated secretory vesicles and are secreted together when a hormone binds to a receptor on the pituitary cells and causes a rise in cytosolic Ca^{2+} . Although these three proteins share no identical amino acid sequences that might serve as a sorting sequence, they must have some common feature that signals their incorporation into regulated secretory vesicles.

Morphologic evidence suggests that sorting into the regulated pathway is controlled by selective protein aggregation. For instance, immature vesicles in this pathway—those that have just budded from the *trans*-Golgi network—contain diffuse aggregates of secreted protein that are visible in the electron microscope. These aggregates also are found in vesicles that are in the process of budding, indicating that proteins destined for regulated secretory vesicles selectively aggregate together before their incorporation into the vesicles.

Other studies have shown that regulated secretory vesicles from mammalian secretory cells contain three proteins, *chromogranin A*, *chromogranin B*, and *secretogranin II*, that together form aggregates when incubated at the ionic conditions (pH 6.5 and 1 mM Ca^{2+}) thought to occur in the *trans*-Golgi network; such aggregates do not form at the neutral pH of the ER. The selective aggregation of regulated secreted proteins together with chromogranin A, chromogranin B, or secretogranin II could be the basis for sorting of these proteins into regulated secretory vesicles. Secreted proteins that

do not associate with these proteins, and thus do not form aggregates, would be sorted into unregulated transport vesicles by default.

Some Proteins Undergo Proteolytic Processing After Leaving the *trans*-Golgi

For some secretory proteins (e.g., growth hormone) and certain viral membrane proteins (e.g., the VSV glycoprotein), removal of the N-terminal ER signal sequence from the nascent chain is the only known proteolytic cleavage required to convert the polypeptide to the mature, active species (see Figure 13-6). However, some membrane and many soluble secretory proteins initially are synthesized as relatively long-lived, inactive precursors, termed *proproteins*, that require further proteolytic processing to generate the mature, active proteins. Examples of proteins that undergo such processing are soluble lysosomal enzymes, many membrane proteins such as influenza hemagglutinin (HA), and secreted proteins such as serum albumin, insulin, glucagon, and the yeast α mating factor. In general, the proteolytic conversion of a proprotein to the corresponding mature protein occurs after the proprotein has been sorted in the *trans*-Golgi network to appropriate vesicles.

In the case of soluble lysosomal enzymes, the proproteins are called *proenzymes*, which are sorted by the M6P receptor as catalytically inactive enzymes. In the late endosome or lysosome a proenzyme undergoes a proteolytic cleavage that generates a smaller but enzymatically active polypeptide. Delaying the activation of lysosomal proenzymes until they reach the lysosome prevents them from digesting macromolecules in earlier compartments of the secretory pathway.

Normally, mature vesicles carrying secreted proteins to the cell surface are formed by fusion of several immature ones containing proprotein. Proteolytic cleavage of proproteins, such as proinsulin, occurs in vesicles after they move away from the *trans*-Golgi network (Figure 14-23). The proproteins of most constitutively secreted proteins (e.g., albumin) are cleaved only once at a site C-terminal to a dibasic recognition sequence such as Arg-Arg or Lys-Arg (Figure 14-24a). Proteolytic processing of proteins whose secretion is regulated generally entails additional cleavages. In the case of proinsulin, multiple cleavages of the single polypeptide chain yields the N-terminal B chain and the C-terminal A chain of mature insulin, which are linked by disulfide bonds, and the central C peptide, which is lost and subsequently degraded (Figure 14-24b).

The breakthrough in identifying the proteases responsible for such processing of secreted proteins came from analysis of yeast with a mutation in the *KEX2* gene. These mutant cells synthesized the precursor of the α mating factor but could not proteolytically process it to the functional form and thus were unable to mate with cells of the opposite mating type (see Figure 16-23). The wild-type *KEX2* gene encodes an endoprotease that cleaves the α -factor precursor at a site C-terminal to Arg-Arg and Lys-Arg residues. Mammals contain

EXPERIMENTAL FIGURE 14-23 **Proteolytic cleavage of proinsulin occurs in secretory vesicles after they have budded from the *trans*-Golgi network.** Serial sections of the Golgi region of an insulin-secreting cell were stained with (a) a monoclonal antibody that recognizes proinsulin but not insulin, or (b) a different antibody that recognizes insulin but not proinsulin. The antibodies, which were bound to electron-opaque gold particles, appear as dark dots in these electron micrographs (see Figure 9-29). Immature secretory vesicles (closed arrowheads) and vesicles budding from the *trans*-Golgi (arrows) stain with the proinsulin antibody but not with insulin antibody. These vesicles contain diffuse protein aggregates that include proinsulin and other regulated secreted proteins. Mature vesicles (open arrowheads) stain with insulin antibody but not with proinsulin antibody and have a dense core of almost crystalline insulin. Since budding and immature secretory vesicles contain proinsulin (not insulin), the proteolytic conversion of proinsulin to insulin must take place in these vesicles after they bud from the *trans*-Golgi network. The inset in (a) shows a proinsulin-rich secretory vesicle surrounded by a protein coat (dashed line). [From L. Orci et al., 1987, *Cell* 49:865; courtesy of L. Orci.]

a family of endoproteases homologous to the yeast KEX2 protein, all of which cleave a protein chain on the C-terminal side of an Arg-Arg or Lys-Arg sequence. One, called *furin*, is found in all mammalian cells; it processes proteins such as albumin that are secreted by the continuous pathway. In contrast, the *PC2* and *PC3* endoproteases are found only in cells that exhibit regulated secretion; these enzymes are localized to regulated secretory vesicles and proteolytically cleave the precursors of many hormones at specific sites.

Several Pathways Sort Membrane Proteins to the Apical or Basolateral Region of Polarized Cells

The plasma membrane of polarized epithelial cells is divided into two domains, **apical** and **basolateral**; tight junctions located between the two domains prevent the movement of plasma-membrane proteins between the domains (see Figure 20-10). Several sorting mechanisms direct newly synthesized membrane proteins to either the apical or basolateral domain of epithelial cells, and any one protein may be sorted by more than one mechanism. As a result of this sorting and the restriction on protein movement within the plasma membrane due to tight junctions, distinct sets of proteins are found in the apical or basolateral domain. This preferential localization of certain transport proteins is critical to a variety of important physiological functions, such as absorption of nutrients from the intestinal lumen and acidification of the stomach lumen (see Figures 11-30 and 11-31).

Microscopic and cell-fractionation studies indicate that proteins destined for either the apical or the basolateral membranes are initially transported together to the membranes of the *trans*-Golgi network. In some cases, proteins destined for the apical membrane are sorted into their own transport vesicles that bud from the *trans*-Golgi network

(a) Proinsulin antibody

(b) Insulin antibody

and then move to the apical region, whereas proteins destined for the basolateral membrane are sorted into other vesicles that move to the basolateral region. The different vesicle types can be distinguished by their protein constituents, including distinct Rab and v-SNARE proteins, which

(a) Constitutive secreted proteins

(b) Regulated secreted proteins

FIGURE 14-24 Proteolytic processing of proproteins in the constitutive and regulated secretion pathways. The processing of proalbumin and proinsulin is typical of the constitutive and regulated pathways, respectively. The endoproteases that function in such processing cleave at the C-terminal side of two consecutive amino acids. (a) The endoprotease furin acts on the precursors of constitutive secreted proteins. (b) Two endoproteases, PC2 and PC3, act on the precursors of regulated secreted proteins. The final processing of many such proteins is catalyzed by a carboxypeptidase that sequentially removes two basic amino acid residues at the C-terminus of a polypeptide. [See D. Steiner et al., 1992, *J. Biol. Chem.* **267**:23435.]

apparently target them to the appropriate plasma-membrane domain. In this mechanism, segregation of proteins destined for either the apical or basolateral membranes occurs as cargo proteins are incorporated into particular types of vesicles budding from the *trans*-Golgi network.

Such direct basolateral-apical sorting has been investigated in cultured Madin-Darby canine kidney (MDCK) cells, a line of cultured polarized epithelial cells (see Figure 9-4). In MDCK cells infected with the influenza virus, progeny viruses bud only from the apical membrane, whereas in cells infected with vesicular stomatitis virus (VSV), progeny viruses bud only from the basolateral membrane. This difference occurs because the HA glycoprotein of influenza virus is transported from the Golgi complex exclusively to the apical membrane and the VSV G protein is transported only to the basolateral membrane (Figure 14-25). Furthermore, when the gene encoding HA protein is introduced into uninfected cells by recombinant DNA techniques, all the expressed HA accumulates in the apical membrane, indicating that the sorting signal resides in the HA glycoprotein itself and not in other viral proteins produced during viral infection.

FIGURE 14-25 Sorting of proteins destined for the apical and basolateral plasma membranes of polarized cells. When cultured MDCK cells are infected simultaneously with VSV and influenza virus, the VSV G glycoprotein (purple) is found only on the basolateral membrane, whereas the influenza HA glycoprotein (green) is found only on the apical membrane. Some cellular proteins (orange circle), especially those with a GPI anchor, are likewise sorted directly to the apical membrane and others to the basolateral membrane (not shown) via specific transport vesicles that bud from the *trans*-Golgi network. In certain polarized cells, some apical and basolateral proteins are transported together to the basolateral surface; the apical proteins (yellow oval) then move selectively, by endocytosis and transcytosis, to the apical membrane. [After K. Simons and A. Wandinger-Ness, 1990, *Cell* **62**:207, and K. Mostovet et al., 1992, *J. Cell Biol.* **116**:577.]

Among the cellular proteins that undergo similar apical-basolateral sorting in the Golgi are those with a *glycosylphosphatidylinositol (GPI) membrane anchor*. In MDCK cells and most other types of epithelial cells, GPI-anchored proteins are targeted to the apical membrane. In membranes GPI-anchored proteins are clustered into lipid rafts, which are rich in sphingolipids (see Chapter 10). This finding suggests that lipid rafts are localized to the apical membrane along with proteins that preferentially partition them in many cells. However, the GPI anchor is not an apical sorting signal in all polarized cells; in thyroid cells, for example, GPI-anchored proteins are targeted to the basolateral membrane. Other than GPI anchors, no unique sequences have been identified that are both necessary and sufficient to target proteins to either the apical or basolateral domain. Instead, each membrane protein may contain multiple sorting signals, any one of which can target it to the appropriate plasma-membrane domain. The identification of such complex signals and of the vesicle coat proteins that recognize them is currently being pursued for a number of different proteins that are sorted to specific plasma-membrane domains of polarized epithelial cells.

Another mechanism for sorting apical and basolateral proteins, also illustrated in Figure 14-25, operates in hepatocytes. The basolateral membranes of hepatocytes face the blood (as in intestinal epithelial cells), and the apical membranes line the small intercellular channels into which bile is secreted. In hepatocytes, newly made apical and basolateral proteins are first transported in vesicles from the *trans*-Golgi network to the basolateral region and incorporated into the plasma membrane by exocytosis (i.e., fusion of the vesicle membrane with the plasma membrane). From there, both basolateral and apical proteins are endocytosed in the same vesicles, but then their paths diverge. The endocytosed basolateral proteins are sorted into transport vesicles that recycle them to the basolateral membrane. In contrast, the apically destined endocytosed proteins are sorted into transport vesicles that move across the cell and fuse with the apical membrane, a process called *transcytosis*. This process also is used to move extracellular materials from one side of an epithelium to another. Even in epithelial cells, such as MDCK cells, in which apical-basolateral protein sorting occurs in the Golgi, transcytosis may provide an editing function by which an apical protein sorted incorrectly to the basolateral membrane would be subjected to endocytosis and then correctly delivered to the apical membrane.

KEY CONCEPTS of Section 14.4

Later Stages of the Secretory Pathway

- The *trans*-Golgi network (TGN) is a major branch point in the secretory pathway where soluble secreted proteins, lysosomal proteins, and in some cells membrane proteins destined for the basolateral or apical plasma membrane are segregated into different transport vesicles.

- Many vesicles that bud from the *trans*-Golgi network as well as endocytic vesicles bear a coat composed of AP (adapter protein) complexes and clathrin (see Figure 14-18).
- Pinching off of clathrin-coated vesicles requires dynamin, which forms a collar around the neck of the vesicle bud and hydrolyzes GTP (see Figure 14-19).
- Soluble enzymes destined for lysosomes are modified in the *cis*-Golgi, yielding multiple mannose 6-phosphate (M6P) residues on their oligosaccharide chains.
- M6P receptors in the membrane of the *trans*-Golgi network bind proteins bearing M6P residues and direct their transfer to late endosomes, where receptors and their ligand proteins dissociate. The receptors then are recycled to the Golgi or plasma membrane, and the lysosomal enzymes are delivered to lysosomes (see Figure 14-22).
- Regulated secreted proteins are concentrated and stored in secretory vesicles to await a neural or hormonal signal for exocytosis. Protein aggregation within the *trans*-Golgi network may play a role in sorting secreted proteins to the regulated pathway.
- Many proteins transported through the secretory pathway undergo post-Golgi proteolytic cleavages that yield the mature, active proteins. Generally, proteolytic maturation can occur in vesicles carrying proteins from the *trans*-Golgi network to the cell surface, in the late endosome, or in the lysosome.
- In polarized epithelial cells, membrane proteins destined for the apical or basolateral domains of the plasma membrane are sorted in the *trans*-Golgi network into different transport vesicles (see Figure 14-25). The GPI anchor is the only apical-basolateral sorting signal identified so far.
- In hepatocytes and some other polarized cells, all plasma-membrane proteins are directed first to the basolateral membrane. Apically destined proteins then are endocytosed and moved across the cell to the apical membrane (transcytosis).

14.5 Receptor-Mediated Endocytosis

In previous sections we have explored the main pathways whereby soluble and membrane secretory proteins synthesized on the rough ER are delivered to the cell surface or other destinations. Cells also can internalize materials from their surroundings and sort these to particular destinations. A few cell types (e.g., macrophages) can take up whole bacteria and other large particles by *phagocytosis*, a nonselective actin-mediated process in which extensions of the plasma membrane envelop the ingested material, forming large vesicles called phagosomes (see Figure 17-19). In contrast, all eukaryotic cells continually engage in endocytosis, a process in which a small region of the plasma membrane invaginates to form a membrane-limited vesicle about 0.05–0.1 μm in diameter. In one form of endocytosis, called *pinocytosis*, small droplets of extracellular fluid and any material dissolved in it

are nonspecifically taken up. Our focus in this section, however, is on **receptor-mediated endocytosis**, in which a specific receptor on the cell surface binds tightly to an extracellular macromolecular ligand that it recognizes; the plasma membrane region containing the receptor-ligand complex then buds inward and pinches off, becoming a transport vesicle.

Among the common macromolecules that vertebrate cells internalize by receptor-mediated endocytosis are cholesterol-containing particles called low-density lipoprotein (LDL), the iron-carrying protein transferrin, many protein hormones (e.g., insulin), and certain glycoproteins. Receptor-mediated endocytosis of such ligands generally occurs via clathrin/AP2-coated pits and vesicles in a process similar to the packaging of lysosomal enzymes by binding of mannose 6-phosphate (M6P) in the *trans*-Golgi network (see Figure 14-22). As noted earlier, some M6P receptors are found on the cell surface, and these participate in the receptor-mediated endocytosis of lysosomal enzymes that are mistakenly secreted. In

general, the transmembrane receptor proteins that function in the uptake of extracellular ligands are internalized from the cell surface during endocytosis and are then sorted and recycled back to the cell surface, much like the recycling of M6P receptors to the plasma membrane and *trans*-Golgi. The rate at which a ligand is internalized is limited by the amount of its corresponding receptor on the cell surface.

Clathrin/AP2 pits make up about 2 percent of the surface of cells such as hepatocytes and fibroblasts. Many internalized ligands have been observed in these pits and vesicles, which are thought to function as intermediates in the endocytosis of most (though not all) ligands bound to cell-surface receptors (Figure 14-26). Some receptors are clustered over clathrin-coated pits even in the absence of ligand. Other receptors diffuse freely in the plane of the plasma membrane but undergo a conformational change when binding to ligand, so that when the receptor-ligand complex diffuses into a clathrin-coated pit, it is retained there. Two or more types

EXPERIMENTAL FIGURE 14-26 The initial stages of receptor-mediated endocytosis of low-density lipoprotein (LDL) particles are revealed by electron microscopy.

Cultured human fibroblasts were incubated in a medium containing LDL particles covalently linked to the electron-dense, iron-containing protein ferritin; each small iron particle in ferritin is visible as a small dot under the electron microscope. Cells initially were incubated at 4 °C; at this temperature LDL can bind to its receptor, but internalization does not occur. After excess LDL not bound to the cells was washed away, the cells were warmed

to 37 °C and then prepared for microscopy at periodic intervals. (a) A coated pit, showing the clathrin coat on the inner (cytosolic) surface of the pit, soon after the temperature was raised. (b) A pit containing LDL apparently closing on itself to form a coated vesicle. (c) A coated vesicle containing ferritin-tagged LDL particles. (d) Ferritin-tagged LDL particles in a smooth-surfaced early endosome 6 minutes after internalization began. [Photographs courtesy of R. Anderson. Reprinted by permission from J. Goldstein et al., *Nature* **279**:679. Copyright 1979, Macmillan Journals Limited. See also M. S. Brown and J. Goldstein, 1986, *Science* **232**:34.]

of receptor-bound ligands, such as LDL and transferrin, can be seen in the same coated pit or vesicle.

Cells Take Up Lipids from the Blood in the Form of Large, Well-Defined Lipoprotein Complexes

Lipids absorbed from the diet in the intestines or stored in adipose tissue can be distributed to cells throughout the body. To facilitate the mass transfer of lipids between cells, animals have evolved an efficient way to package from hundreds to thousands of lipid molecules into water-soluble, macromolecular carriers, called **lipoproteins**, that cells can take up from the circulation as an ensemble. A lipoprotein particle has a shell composed of proteins (*apolipoproteins*) and a cholesterol-containing phospholipid monolayer. The shell is amphipathic because its outer surface is hydrophilic, making these particles water soluble, and its inner surface is hydrophobic. Adjacent to the hydrophobic inner surface of the shell is a core of neutral lipids containing mostly cholesteryl esters, triglycerides, or both. Mammalian lipoproteins fall into different classes, defined by their differing buoyant densities. The class we will consider here is **low-density lipoprotein (LDL)**. A typical LDL particle, depicted in Figure 14-27, is a sphere 20–25 nm in diameter. The amphipathic outer shell is composed of a phospholipid monolayer and a single molecule of a large protein known as *apoB-100*; the

FIGURE 14-27 Model of low-density lipoprotein (LDL). This class and the other classes of lipoproteins have the same general structure: an amphipathic shell, composed of a phospholipid monolayer (not bilayer), cholesterol, and protein, and a hydrophobic core, composed mostly of cholesteryl esters or triglycerides or both but with minor amounts of other neutral lipids (e.g., some vitamins). This model of LDL is based on electron microscopy and other low-resolution biophysical methods. LDL is unique in that it contains only a single molecule of one type of apolipoprotein (*apoB*), which appears to wrap around the outside of the particle as a band of protein. The other lipoproteins contain multiple apolipoprotein molecules, often of different types. [Adapted from M. Krieger, 1995, in E. Haber, ed., *Molecular Cardiovascular Medicine*, Scientific American Medicine, pp. 31–47.]

core of the particle is packed with cholesterol in the form of cholesteryl esters.

Two general experimental approaches have been used to study how LDL particles enter cells. The first method makes use of LDL that has been labeled by the covalent attachment of radioactive ^{125}I to the side chains of tyrosine residues in *apoB-100* on the surfaces of the LDL particles. After cultured cells are incubated for several hours with the labeled LDL, it is possible to determine how much LDL is bound to the surfaces of cells, how much is internalized, and how much of the *apoB-100* component of the LDL is degraded by enzymatic hydrolysis to individual amino acids. The degradation of *apoB-100* can be detected by the release of ^{125}I -tyrosine into the culture medium. Figure 14-28 shows the time course of events in receptor-mediated cellular LDL processing, determined by pulse-chase experiments with a fixed concentration of ^{125}I -labeled LDL. These experiments clearly demonstrate the order of events: surface binding of LDL $\rightarrow$ internalization $\rightarrow$ degradation. The second approach involves tagging LDL particles with an electron-dense label that can be detected by electron microscopy. Such studies can reveal the details of how LDL particles first bind to the surface of cells at clathrin-coated endocytic pits and then remain associated with the coated pits as they invaginate and bud off to form coated vesicles and finally are transported to endosomes (see Figure 14-26).

EXPERIMENTAL FIGURE 14-28 Pulse-chase experiment demonstrates precursor-product relations in cellular uptake of LDL.

Cultured normal human skin fibroblasts were incubated in a medium containing ^{125}I -LDL for 2 hours at 4 °C (the pulse). After excess ^{125}I -LDL not bound to the cells was washed away, the cells were incubated at 37 °C for the indicated amounts of time in the absence of external LDL (the chase). The amounts of surface-bound, internalized, and degraded (hydrolyzed) ^{125}I -LDL were measured. Binding but not internalization or hydrolysis of LDL *apoB-100* occurs during the 4 °C pulse. The data show the very rapid disappearance of bound ^{125}I -LDL from the surface as it is internalized after the cells have been warmed to allow membrane movements. After a lag period of 15–20 minutes, lysosomal degradation of the internalized ^{125}I -LDL commences.

[See M. S. Brown and J. L. Goldstein, 1976, *Cell* 9:663.]

Receptors for Low-Density Lipoprotein and Other Ligands Contain Sorting Signals That Target Them for Endocytosis

The key to understanding how LDL particles bind to the cell surface and are then taken up into endocytic vesicles came from discovery of the *LDL receptor (LDLR)*. The LDL receptor is an 839-residue glycoprotein with a single transmembrane segment; it has a short C-terminal cytosolic segment and a long N-terminal extracellular segment that contains the LDL-binding

domain. Seven cysteine-rich repeats form the ligand-binding domain, which interacts with the apoB-100 molecule in an LDL particle. Figure 14-29 shows how LDL receptor proteins facilitate internalization of LDL particles by receptor-mediated endocytosis. After internalized LDL particles reach lysosomes, lysosomal proteases hydrolyze their surface apolipoproteins and lysosomal cholesteryl esterases hydrolyze their core cholesteryl esters. The unesterified cholesterol is then free to leave the lysosome and be used as necessary by the cell in the synthesis of membranes or various cholesterol derivatives.

FIGURE 14-29 Endocytic pathway for internalizing low-density lipoprotein (LDL). Step **1**: Cell-surface LDL receptors bind to an apoB protein embedded in the phospholipid outer layer of LDL particles. Interaction between the NPXY sorting signal in the cytosolic tail of the LDL receptor and the AP2 complex incorporates the receptor-ligand complex into forming endocytic vesicles. Step **2**: Clathrin-coated pits (or buds) containing receptor-LDL complexes are pinched off by the same dynamin-mediated mechanism used to form clathrin/AP1 vesicles on the *trans*-Golgi network (see Figure 14-19). Step **3**: After the vesicle coat is shed, the uncoated endocytic vesicle (early endo-

some) fuses with the late endosome. The acidic pH in this compartment causes a conformational change in the LDL receptor that leads to release of the bound LDL particle. Step **4**: The late endosome fuses with the lysosome, and the proteins and lipids of the free LDL particle are broken down to their constituent parts by enzymes in the lysosome. Step **5**: The LDL receptor recycles to the cell surface, where at the neutral pH of the exterior medium the receptor undergoes a conformational change so that it can bind another LDL particle. [See M. S. Brown and J. L. Goldstein, 1986, *Science* **232**:34, and G. Rudenko et al., 2002, *Science* **298**:2353.]

The discovery of the LDL receptor and an understanding of how it functions came from studying cells from patients with *familial hypercholesterolemia (FH)*, a hereditary disease that is marked by elevated plasma LDL cholesterol and is now known to be caused by mutations in the *LDLR* gene. In patients who have one normal and one defective copy of the *LDLR* gene (heterozygotes), LDL cholesterol in the blood is increased about twofold. Those with two defective *LDLR* genes (homozygotes) have LDL cholesterol levels that are from fourfold to sixfold as high as normal. FH heterozygotes commonly develop cardiovascular disease about 10 years earlier than normal people do, and FH homozygotes usually die of heart attacks before reaching their late 20s.

A variety of mutations in the gene encoding the LDL receptor can cause familial hypercholesterolemia. Some mutations prevent the synthesis of the LDLR protein; others prevent proper folding of the receptor protein in the ER, leading to its premature degradation (Chapter 13); still other mutations reduce the ability of the LDL receptor to bind LDL tightly. A particularly informative group of mutant receptors are expressed on the cell surface and bind LDL normally but cannot mediate the internalization of bound LDL. In individuals with this type of defect, plasma-membrane receptors for other ligands are internalized normally, but the mutant LDL receptor is not recruited into coated pits. Analysis of this mutant receptor and other mutant LDL receptors generated experimentally and expressed in fibroblasts identified a four-residue motif in the cytosolic segment of the receptor that is crucial for its internalization: Asn-Pro-X-Tyr, where X can be any amino acid. This *NPXY sorting signal* binds to the AP2 complex, linking the clathrin/AP2 coat to the cytosolic segment of the LDL receptor in coated pits. A mutation in any of the conserved residues of the NPXY signal will abolish the ability of the LDL receptor to be incorporated into coated pits.

A small number of individuals who exhibit the usual symptoms associated with familial hypercholesterolemia produce normal LDL receptors. In these individuals, the gene encoding the AP2 subunit protein that binds the NPXY sorting signal is defective. As a result, LDL receptors are not incorporated into clathrin/AP2 vesicles and endocytosis of LDL particles is compromised. Analysis of patients with this genetic disorder highlights the importance of adapter proteins in protein trafficking mediated by clathrin vesicles. ■

Mutational studies have shown that other cell-surface receptors can be directed into forming clathrin/AP2 pits by a YXXF sorting signal. Recall from our earlier discussion that this same sorting signal recruits membrane proteins into clathrin/AP1 vesicles that bud from the *trans*-Golgi network by binding to a subunit of AP1 (see Table 14-2). All these observations indicate that YXXF is a widely used signal for sorting membrane proteins to clathrin-coated vesicles.

In some cell-surface proteins, however, other sequences (e.g., Leu-Leu) or covalently linked ubiquitin molecules signal endocytosis. Among the proteins associated with clathrin/AP2 vesicles, several contain domains that specifically bind to ubiquitin, and it has been hypothesized that these vesicle-associated proteins mediate the selective incorporation of ubiquitinated membrane proteins into endocytic vesicles. As described later, the ubiquitin tag on endocytosed membrane proteins is also recognized at a later stage in the endocytic pathway and plays a role in delivering these proteins into the interior of the lysosome, where they are degraded.

The Acidic pH of Late Endosomes Causes Most Receptor-Ligand Complexes to Dissociate

The overall rate of endocytic internalization of the plasma membrane is quite high: cultured fibroblasts regularly internalize 50 percent of their cell-surface proteins and phospholipids each hour. Most cell-surface receptors that undergo endocytosis will repeatedly deposit their ligands within the cell and then recycle to the plasma membrane, once again to mediate internalization of ligand molecules. For instance, the LDL receptor makes one round trip into and out of the cell interior every 10–20 minutes, for a total of several hundred trips in its 20-hour life span.

Internalized receptor-ligand complexes commonly follow the pathway depicted for the M6P receptor in Figure 14-22 and the LDL receptor in Figure 14-29. Endocytosed cell-surface receptors typically dissociate from their ligands within late endosomes, which appear as spherical vesicles with tubular branching membranes located a few micrometers from the cell surface. The original experiments that defined the late endosome sorting vesicle utilized the asialoglycoprotein receptor. This liver-specific protein mediates the binding and internalization of abnormal glycoproteins whose oligosaccharides terminate in galactose rather than the normal sialic acid; hence the name *asialoglycoprotein*. Electron microscopy of liver cells perfused with asialoglycoprotein reveal that 5–10 minutes after internalization, ligand molecules are found in the lumen of late endosomes, while the tubular membrane extensions are rich in receptor and rarely contain ligand. These findings indicate that the late endosome is the organelle in which receptors and ligands are uncoupled.

The dissociation of receptor-ligand complexes in late endosomes occurs not only in the endocytic pathway but also in the delivery of soluble lysosomal enzymes via the secretory pathway (see Figure 14-22). As discussed in Chapter 11, the membranes of late endosomes and lysosomes contain V-class proton pumps that act in concert with Cl^- channels to acidify the vesicle lumen (see Figure 11-14). Most receptors, including the M6P receptor and cell-surface receptors for LDL particles and asialoglycoprotein, bind their ligands tightly at

FIGURE 14-30 Model for pH-dependent binding of LDL particles by the LDL receptor. Schematic depiction of an LDL receptor at the neutral pH found at the cell surface (a) and at the acidic pH found in the interior of the late endosome (b). (a) At the cell surface, apoB-100 on the surface of an LDL particle binds tightly to the receptor. Of the seven repeats (R1–R7) in the ligand-binding arm, R4 and R5 appear to be most critical for LDL binding. (b, top) Within the endosome, histidine residues in the β -propeller domain of the LDL receptor become protonated. The positively charged propeller can bind with high affinity to the ligand-binding arm, which contains negatively charged residues, causing release of the LDL particle. (b, bottom) Experimental electron density and C_α trace model of the extracellular region of the LDL receptor at pH 5.3 based on x-ray crystallographic analysis. In this conformation, extensive hydrophobic and ionic interactions occur between the β propeller and the R4 and R5 repeats. [Part (b) from G. Rudenko et al., 2002, *Science* 298:2353.]

neutral pH but release their ligands if the pH is lowered to 6.0 or below. The late endosome is the first vesicle encountered by receptor-ligand complexes whose luminal pH is sufficiently acidic to promote dissociation of most endocytosed receptors from their tightly bound ligands.

The mechanism by which the LDL receptor releases bound LDL particles is now understood in detail (Figure 14-30). At the endosomal pH of 5.0–5.5, histidine residues in a region known as the β -propeller domain of the receptor become protonated, forming a site that can bind with high affinity to the negatively charged repeats in the LDL-binding domain. This intramolecular interaction sequesters the repeats in a conformation that cannot simultaneously bind to apoB-100, thus causing release of the bound LDL particle.

The Endocytic Pathway Delivers Iron to Cells Without Dissociation of the Receptor-Transferrin Complex in Endosomes

The endocytic pathway involving the transferrin receptor and its ligand differs from the LDL pathway in that the receptor-ligand complex does not dissociate in late endosomes. Nonetheless, changes in pH also mediate the sorting of receptors and ligands in the transferrin pathway, which functions to deliver iron to cells.

A major glycoprotein in the blood, transferrin transports iron to all tissue cells from the liver (the main site of iron

storage in the body) and from the intestine (the site of iron absorption). The iron-free form, *apotransferrin*, binds two Fe^{3+} ions very tightly to form *ferrotransferrin*. All mammalian cells contain cell-surface transferrin receptors that avidly bind ferrotransferrin at neutral pH, after which the receptor-bound ferrotransferrin is subjected to endocytosis. Like the components of an LDL particle, the two bound Fe^{3+} atoms remain in the cell, but the apotransferrin part of the ligand does not dissociate from the receptor in the late endosome, and within minutes after being endocytosed, apotransferrin is returned to the cell surface and secreted from the cell.

As depicted in Figure 14-31, the explanation for the behavior of the transferrin receptor-ligand complex lies in the unique ability of apotransferrin to remain bound to the transferrin receptor at the low pH (5.0–5.5) of late endosomes. At a pH of less than 6.0, the two bound Fe^{3+} atoms dissociate from ferrotransferrin, are reduced to Fe^{2+} by an unknown mechanism, and then are exported into the cytosol by an endosomal transporter specific for divalent metal ions. The receptor-apotransferrin complex remaining after dissociation of the iron atoms is recycled back to the cell surface. Although apotransferrin binds tightly to its receptor at a pH of 5.0 or 6.0, it does not bind at neutral pH. Hence the bound apotransferrin dissociates from the transferrin receptor when the recycling vesicles fuse with the plasma membrane and the receptor-ligand complex encounters the neutral pH of the extracellular interstitial fluid or growth medium. The recycled receptor is then free to bind another

FIGURE 14-31 The transferrin cycle, which operates in all growing mammalian cells. Step **1**: The transferrin dimer carrying two bound atoms of Fe^{3+} , called ferrotransferrin, binds to the transferrin receptor at the cell surface. Step **2**: Interaction between the tail of the transferrin receptor and the AP2 adapter complex incorporates the receptor-ligand complex into endocytic clathrin-coated vesicles. Steps **3** and **4**: The vesicle coat is shed and the endocytic vesicles fuse

with the membrane of the endosome. Fe^{3+} is released from the receptor-ferrotransferrin complex in the acidic late endosome compartment. Step **5**: The apotransferrin protein remains bound to its receptor at this pH, and they recycle to the cell surface together. Step **6**: The neutral pH of the exterior medium causes release of the iron-free apotransferrin. [See A. Ciechanover et al., 1983, *J. Biol. Chem.* **258**:9681.]

molecule of ferrotransferrin, and the released apotransferrin is carried in the bloodstream to the liver or intestine to be reloaded with iron.

KEY CONCEPTS of Section 14.5

Receptor-Mediated Endocytosis

- Some extracellular ligands that bind to specific cell-surface receptors are internalized, along with their receptors, in clathrin-coated vesicles whose coats also contain AP2 complexes (see Figure 14-26).

- Sorting signals in the cytosolic domain of cell-surface receptors target them into clathrin/AP2-coated pits for internalization. Known signals include the Asn-Pro-X-Tyr, Tyr-X-X- Φ , and Leu-Leu sequences (see Table 14-2).

- The endocytic pathway delivers some ligands (e.g., LDL particles) to lysosomes, where they are degraded. Transport vesicles from the cell surface first fuse with late endosomes, which subsequently fuse with the lysosome.

- Most receptor-ligand complexes dissociate in the acidic milieu of the late endosome; the receptors are recycled to the plasma membrane, while the ligands are sorted to lysosomes (see Figure 14-29).

- Iron is imported into cells by an endocytic pathway in which Fe^{3+} ions are released from ferrotransferrin in the late endosome. The receptor-apotransferrin complex is recycled to the cell surface, where the complex dissociates, releasing both the receptor and apotransferrin for reuse.

14.6 Directing Membrane Proteins and Cytosolic Materials to the Lysosome

The major function of lysosomes is to degrade extracellular materials taken up by the cell and intracellular components under certain conditions. Materials to be degraded must be delivered to the lumen of the lysosome, where the various degradative enzymes reside. As just discussed, endocytosed ligands (e.g., LDL particles) that dissociate from their receptors in the late endosome subsequently enter the lysosomal lumen when the membrane of the late endosome fuses with the membrane of the lysosome (see Figure 14-29). Likewise, phagosomes carrying bacteria or other particulate matter can fuse with lysosomes, releasing their contents into the lumen for degradation.

It is apparent how the general vesicular trafficking mechanism discussed in this chapter can be used to deliver the luminal contents of an endosomal organelle to the lumen of the lysosome for degradation. However, membrane proteins delivered to the lysosome by the typical vesicular trafficking process we have discussed in this chapter should ultimately be delivered to the membrane of the lysosome. How then are membrane proteins degraded by the lysosome? As we will see in this section, the cell has two different specialized pathways for delivery of materials to the lysosomal lumen for degradation, one for membrane proteins and one for cytosolic materials. The first pathway, used to degrade endocytosed membrane proteins, utilizes an unusual type of vesicle that buds into the lumen of the endosome to produce a multivesicular endosome. The second pathway, known as **autophagy**, involves the *de novo* formation of a double membrane organelle known as an autophagosome that envelops cytosolic material, such as soluble cytosolic proteins or sometimes organelles such as peroxisomes or mitochondria. Both pathways lead to fusion of either the multivesicular endosome or autophagosome with the lysosome, depositing the contents of these organelles into the lysosomal lumen for degradation.

Multivesicular Endosomes Segregate Membrane Proteins Destined for the Lysosomal Membrane from Proteins Destined for Lysosomal Degradation

Resident lysosomal proteins, such as V-class proton pumps and amino acid transporters, can carry out their functions and remain in the lysosomal membrane, where they are protected from degradation by the soluble hydrolytic enzymes in the lumen. Such proteins are delivered to the lysosomal

membrane by transport vesicles that bud from the *trans*-Golgi network by the same basic mechanisms described in earlier sections. In contrast, endocytosed membrane proteins such as receptor proteins that are to be degraded are transferred in their entirety to the interior of the lysosome by a specialized delivery mechanism. Lysosomal degradation of cell-surface receptors for extracellular signaling molecules is a common mechanism for controlling the sensitivity of cells to such signals (Chapter 15). Receptors that become damaged also are targeted for lysosomal degradation.

Early evidence that membranes can be delivered to the lumen of compartments came from electron micrographs showing membrane vesicles and fragments of membranes within endosomes and lysosomes. Parallel experiments in yeast revealed that endocytosed receptor proteins targeted to the vacuole (the yeast organelle equivalent to the lysosome) were primarily associated with membrane fragments and small vesicles within the interior of the vacuole rather than with the vacuole surface membrane.

These observations suggest that endocytosed membrane proteins can be incorporated into specialized vesicles that form at the endosomal membrane (Figure 14-32). Although these vesicles are similar in size and appearance to transport vesicles, they differ topologically. Transport vesicles bud *outward* from the surface of a donor organelle into the cytosol, whereas vesicles within the endosome bud *inward* from the surface into the lumen (away from the cytosol). Mature endosomes containing numerous vesicles in their interior are usually called *multivesicular endosomes* (or bodies). The surface membrane of a multivesicular endosome fuses with the membrane of a lysosome, thereby delivering its internal vesicles and the membrane proteins they contain into the lysosome interior for degradation. Thus the sorting of proteins in the endosomal membrane determines which ones will remain on the lysosome surface (e.g., pumps and transporters) and which ones will be incorporated into internal vesicles and ultimately degraded in lysosomes.

Many of the proteins required for inward budding of the endosomal membrane were first identified by mutations in yeast that blocked delivery of membrane proteins to the interior of the vacuole. More than 10 such “budding” proteins have been identified in yeast, most with significant similarities to mammalian proteins that evidently perform the same function in mammalian cells. The current model of endosomal budding to form multivesicular endosomes in mammalian cells is based primarily on studies in yeast (Figure 14-33). Most cargo proteins that enter the multivesicular endosome are tagged with ubiquitin. Cargo proteins destined to enter the multivesicular endosome usually receive their ubiquitin tag at the plasma membrane, the TGN, or the endosomal membrane. We have already seen how ubiquitin tagging can serve as a signal for degradation of cytosolic or misfolded ER proteins by the proteasome (see Chapters 3 and 13). When used as a signal for proteasomal degradation, the ubiquitin tag usually consists of a chain of covalently linked ubiquitin molecules (polyubiquitin), whereas ubiquitin used to tag proteins for entry into the multivesicular endosome usually takes the form of a single (monoubiquitin) molecule. In the membrane

FIGURE 14-32 Delivery of plasma-membrane proteins to the lysosomal interior for degradation. Early endosomes carrying endocytosed plasma-membrane proteins (blue) and vesicles carrying lysosomal membrane proteins (green) from the *trans*-Golgi network fuse with the late endosome, transferring their membrane proteins to the endosomal membrane (steps **1** and **2**). Proteins to be degraded, such as those from the early endosome, are incorporated into vesicles that bud *into* the interior of the late endosome, eventually forming a

multivesicular endosome containing many such internal vesicles (step **3**). Fusion of a multivesicular endosome directly with a lysosome releases the internal vesicles into the lumen of the lysosome, where they can be degraded (step **4**). Because proton pumps and other lysosomal membrane proteins normally are not incorporated into internal endosomal vesicles, they are delivered to the lysosomal membrane and are protected from degradation. [See F. Reggiori and D. J. Klionsky, 2002, *Eukaryot. Cell* 1:11, and D. J. Katzmann et al., 2002, *Nature Rev. Mol. Cell Biol.* 3:893.]

of the endosome a ubiquitin-tagged peripheral membrane protein, known as Hrs, facilitates recruitment of a set of three different protein complexes to the membrane. These *ESCRT* (endosomal sorting complexes required for transport) proteins include the ubiquitin-binding protein Tsg101. The membrane-associated *ESCRT* proteins act to drive vesicle budding directed into the interior of the endosome as well as loading of specific monoubiquitinated membrane cargo proteins into the

vesicle buds. Finally the *ESCRT* proteins pinch off the vesicle, releasing it and the specific membrane cargo proteins it carries into the interior of the endosome. An ATPase, known as Vps4, uses the energy from ATP hydrolysis to disassemble the *ESCRT* proteins, releasing them into the cytosol for another round of budding. In the fusion event that pinches off a completed endosomal vesicle, the *ESCRT* proteins and Vps4 may function like SNAREs and NSF, respectively, in

FIGURE 14-33 Model of the mechanism for formation of multivesicular endosomes. In endosomal budding, ubiquitinated Hrs on the endosomal membrane directs loading of specific membrane cargo proteins (blue) into vesicle buds and then recruits cytosolic *ESCRT* proteins to the membrane (step **1**). Note that both Hrs and the recruited cargo proteins are tagged with ubiquitin. After the set of bound *ESCRT* complexes mediate the completion and pinching off of the inwardly budding vesicles (step **2**), they are disassembled by the ATPase Vps4 and returned to the cytosol (step **3**). See text for discussion. [Adapted from O. Pornillos et al., 2002, *Trends Cell Biol.* 12:569.]

the typical membrane-fusion process discussed previously (see Figure 14-10).

Retroviruses Bud from the Plasma Membrane by a Process Similar to Formation of Multivesicular Endosomes

The vesicles that bud into the interior of endosomes have a topology similar to that of enveloped virus particles that bud from the plasma membrane of virus-infected cells. Moreover, recent experiments demonstrate that a common set of proteins is required for both types of membrane-budding events. In fact, the two processes so closely parallel each other in mechanistic detail as to suggest that enveloped viruses have evolved mechanisms to recruit the cellular proteins used in inward endosomal budding for their own purposes.

The human immunodeficiency virus (HIV) is an enveloped retrovirus that buds from the plasma membrane of infected cells in a process driven by viral Gag protein, the major structural component of completed virus particles. Gag protein

binds to the plasma membrane of an infected cell and ~4000 Gag molecules polymerize into a spherical shell, producing a structure that looks like a vesicle bud protruding outward from the plasma membrane. Mutational studies with HIV have revealed that the N-terminal segment of Gag protein is required for association with the plasma membrane, whereas the C-terminal segment is required for pinching off of complete HIV particles. For instance, if the portion of the viral genome encoding the C-terminus of Gag is removed, HIV buds will form in infected cells, but pinching off does not occur, and thus no free virus particles are released.

The first indication that HIV budding employs the same molecular machinery as vesicle budding into endosomes came from the observation that Tsg101, an ESCRT protein, binds to the C-terminus of Gag protein. Subsequent findings have clearly established the mechanistic parallels between the two processes. For example, Gag is ubiquitinated as part of the process of virus budding, and in cells with mutations in Tsg101 or Vps4, HIV virus buds accumulate but cannot pinch off from the membrane (Figure 14-34). Moreover,

PODCAST: HIV Budding from the Plasma Membrane

FIGURE 14-34 Mechanism for budding of HIV from the plasma membrane. Proteins required for formation of multivesicular endosomes are exploited by HIV for virus budding from the plasma membrane. (a) Budding of HIV particles from HIV-infected cells occurs by a similar mechanism as in Figure 14-33, using the virally encoded Gag protein and cellular ESCRT and Vps4 (steps 1–3). Ubiquitinated Gag near a budding particle functions like Hrs. See text for discussion. (b) In wild-type cells infected with HIV, virus particles bud from the plasma membrane and are rapidly released into the extracellular space. (c) In cells that lack the functional ESCRT protein Tsg101, the viral Gag protein forms dense viruslike structures, but budding of these structures from the plasma membrane cannot be completed and chains of incomplete viral buds still attached to the plasma membrane accumulate. [Wes Sundquist, University of Utah.]

when a segment from the cellular Hrs protein is added to a truncated Gag protein by construction of the appropriate hybrid gene, proper budding and release of virus particles is restored. Taken together, these results indicate that Gag protein mimics the function of Hrs, redirecting ESCRT proteins to the plasma membrane, where they can function in the budding of virus particles.

Other enveloped retroviruses such as murine leukemia virus and Rous sarcoma virus also have been shown to require ESCRT complexes for their budding, although each virus appears to have evolved a somewhat different mechanism to recruit ESCRT complexes to the site of virus budding.

The Autophagic Pathway Delivers Cytosolic Proteins or Entire Organelles to Lysosomes

When cells are placed under stress such as conditions of starvation, they have the capacity to recycle macromolecules for use as nutrients in a process of lysosomal degradation known as **autophagy** (“eating oneself”). The autophagic pathway involves the formation of a flattened double-membrane cup-shaped structure that envelops a region of the cytosol or an entire organelle (e.g., mitochondrion), forming an *autophagosome*, or *autophagic vesicle* (Figure 14-35). The outer membrane of an autophagic vesicle can fuse with the lysosome, delivering a large vesicle, bounded by a single membrane bilayer, to the interior of the lysosome. Similar to the

situation that occurs when the contents of multivesicular endosomes are delivered to the lysosome, lipases and proteases within the lysosome will degrade the autophagic vesicle and its contents into their molecular components. Amino acid permeases in the lysosomal membrane then allow for transport of free amino acids back into the cytosol for use in synthesis of new proteins.

By studying mutants defective in the autophagic pathway, scientists have identified processes other than recycling of cellular components during starvation that also depend on autophagy. Experiments carried out principally in *Drosophila* and mice have shown that autophagy participates in a type of quality control that removes organelles that have ceased to function properly. In particular, the autophagic pathway can target for destruction dysfunctional mitochondria that have lost their integrity and no longer have an electrochemical gradient across their inner membrane. In certain cell types, pathogenic bacteria and viruses that are multiplying in the cytosol of host cells can be targeted to the autophagic pathway for destruction in the lysosome as part of a host defense mechanism against infection.

For each of these processes and in all eukaryotic organisms the autophagic pathway takes place in three basic steps. Although the underlying mechanisms for each of these steps are relatively poorly understood, they are thought to be related to the basic mechanisms for vesicular trafficking discussed in this chapter.

FIGURE 14-35 The autophagic pathway. The autophagic pathway allows cytosolic proteins and organelles to be delivered to the lysosomal interior for degradation. In the autophagic pathway, a cup-shaped structure forms around portions of the cytosol (*right*) or an organelle such as a mitochondrion as shown here (*left*). Continued addition of membrane eventually leads to the formation of an autophagosome vesicle that envelops its contents by two complete membranes (step **1**). Fusion of the outer membrane with the

membrane of a lysosome releases a single-layer vesicle and its contents into the lysosome interior (step **2**). After degradation of the protein and lipid components by hydrolases in the lysosome interior, the released amino acids are transported across the lysosomal membrane into the cytosol. Proteins known to participate in the autophagic pathway include Atg8, which forms a coat structure around the autophagosome.

Autophagic Vesicle Nucleation The autophagic vesicle is thought to originate from a fragment of a membrane-bounded organelle. The origin of this membrane has been difficult to trace because no known integral membrane proteins, which might serve to identify the source of this membrane, are known to be required for the formation of the autophagic vesicle. Studies in yeast have shown that some mutants defective in Golgi trafficking are also defective in autophagy, suggesting that the autophagic vesicle is initially derived from a fragment of the Golgi. Autophagy that is induced by starvation appears to be a nonspecific process in which a random portion of the cytoplasm, including organelles, becomes enveloped by an autophagosome. In these cases, the site of nucleation is probably random. In cases in which defective organelles are enveloped by the autophagosome, some type of signal or binding site must be present on the surface of the organelle to target nucleation of the autophagic vesicle.

Autophagic Vesicle Growth and Completion New membrane must be delivered to the autophagosome membrane in order for this cup-shaped organelle to grow. This growth is likely to occur by the fusion of transport vesicles with the membrane of the autophagosome. About 30 proteins that participate in the formation of autophagosomes have been identified in genetic screens for yeast mutants that are defective in autophagy. One of these proteins is Atg8, shown in Figure 14-35, which is covalently linked to the lipid phosphatidylethanolamine and thus becomes attached to the cytoplasmic leaflet of the autophagic vesicle. Association of Atg8 with a membrane vesicle appears to be the key step in enabling a vesicle to fuse with the growing autophagosome.

Fusion of Atg8-containing vesicles with the autophagosome involves the formation of a cytosolic assembly of Atg12, Atg5, and Atg16. Atg12 is similar in structure to ubiquitin, and a set of proteins related to ubiquitin-conjugating enzymes are responsible for covalently joining Atg12 to Atg5, by a process similar to that used for covalently joining ubiquitin to a target protein (see Figure 3-29). The covalently linked Atg12-Atg5 dimer then co-assembles with Atg16 to form a polymeric complex localized to the site of growing autophagosomes. By an unknown mechanism this cytosolic complex is thought to bring about the fusion of Atg8-containing vesicles into a cup-shaped autophagosome.

Autophagic Vesicle Targeting and Fusion The outer membrane of the completed autophagosome is thought to contain a set of proteins that target fusion with the membrane of the lysosome. Two vesicle-tethering proteins have been found to be required for autophagosome fusion with the lysosome, but the corresponding SNARE proteins have not been identified. Fusion of the autophagosome with the lysosome occurs after Atg8 has been released from the membrane by proteolytic cleavage, and this proteolysis step only occurs once the autophagic vesicle has completely formed a sealed double-membrane system. Thus Atg8 protein appears to mask fusion proteins and to prevent premature fusion of the autophagosome with the lysosome.

KEY CONCEPTS of Section 14.6

Directing Membrane Proteins and Cytosolic Materials to the Lysosome

- Endocytosed membrane proteins destined for degradation in the lysosome are incorporated into vesicles that bud into the interior of the endosome. Multivesicular endosomes, which contain many of these internal vesicles, can fuse with the lysosome to deliver the vesicles to the interior of the lysosome (see Figure 14-32).
- Some of the cellular components (e.g., ESCRT) that mediate inward budding of endosomal membranes are used in the budding and pinching off of enveloped viruses such as HIV from the plasma membrane of virus-infected cells (see Figures 14-33 and 14-34).
- A portion of the cytoplasm or an entire organelle (e.g., a mitochondrion) can be enveloped in a flattened membrane and eventually incorporated into a double-membrane autophagic vesicle. Fusion of the outer vesicle membrane with the lysosome delivers the enveloped contents to the interior of the lysosome for degradation (see Figure 14-35).

Perspectives for the Future

The biochemical, genetic, and structural information presented in this chapter shows that we now have a basic understanding of how protein traffic flows from one membrane-bounded cellular compartment to another. Our understanding of these processes has come largely from experiments on the function of various types of transport vesicles. These studies have led to the identification of many vesicle components and the discovery of how these components work together to drive vesicle budding, to incorporate the correct set of cargo molecules from the donor organelle, and then to mediate fusion of a completed vesicle with the membrane of a target organelle.

Despite these advances, there is still much to learn about important stages of the secretory and endocytic pathways. For example, we do not yet know what types of proteins form the coats of either the regulated or the constitutive secretory vesicles that bud from the *trans*-Golgi network. In the same vein, we do not know what feature of the Golgi membrane determines whether a COPI-coated vesicle or a clathrin/AP-coated vesicle will bud from it. In both cases, binding of ARF protein to the Golgi membrane appears to initiate vesicle budding. Moreover, the types of signals on cargo proteins that might target them for packaging into secretory vesicles have not yet been defined.

Another baffling process is the formation of vesicles that bud away from the cytosol, such as the vesicles that enter multivesicular endosomes. Although some of the proteins that participate in formation of these “internal” endosome vesicles are known, we do not know what determines their shape or what type of process causes them to pinch off from the donor membrane. Similarly, the origin and growth of the

membrane of the autophagic vesicle is also poorly understood. In the future, it should be possible for these and other poorly understood vesicle-trafficking steps to be dissected through the use of the same powerful combination of biochemical and genetic methods that have delineated the working parts of COPI, COPII, and clathrin/AP vesicles.

In addition to understanding the basic mechanisms that direct the trafficking of cargo proteins in the secretory and endocytic pathways, a major goal of research in this area is to define all of the signals that direct proteins to specific intracellular locations. Although a number of such sequences are known (see Table 14-2), we are only beginning to compile a catalog of these targeting signals and the context in which they are read. The ultimate goal will be to deduce, starting with just the primary coding sequence of any given gene, the trafficking pattern and intracellular location of the gene's protein product. Our ability to fully extract biological information from genomic sequences will be realized only when we have the capability of reading trafficking information from primary protein sequences.

Key Terms

AP (adapter protein) complexes 646	multivesicular endosomes 661
anterograde transport 640	Rab proteins 638
ARF protein 635	receptor-mediated endocytosis 655
autophagy 661	regulated secretion 651
cisternal maturation 629	retrograde transport 640
clathrin 634	<i>sec</i> mutants 632
constitutive secretion 651	secretory pathway 627
COPI 634	sorting signals 637
COPII 634	transcytosis 654
dynamamin 647	<i>trans</i> -Golgi network (TGN) 629
endocytic pathway 627	transport vesicles 627
ESCRT proteins 000	t-SNAREs 634
late endosome 629	v-SNAREs 634
low-density lipoprotein (LDL) 656	
mannose 6-phosphate (M6P) 648	

Review the Concepts

1. The studies of Palade and colleagues used pulse-chase labeling with radioactively labeled amino acids and autoradiography to visualize the location of newly synthesized proteins in pancreatic acinar cells. These early experiments provided invaluable information on protein synthesis and intercompartmental transport. New methods have replaced these early approaches, but two basic requirements are still necessary for any assay to study this type of protein transport. What are they and how do recent experimental approaches meet these criteria?

2. Vesicle budding is associated with coat proteins. What is the role of coat proteins in vesicle budding? How are coat proteins recruited to membranes? What kinds of molecules are likely to be included or excluded from newly formed vesicles? What is the best-known example of a protein likely to be involved in vesicle pinching off?

3. Treatment of cells with the drug brefeldin A (BFA) has the effect of decoating Golgi apparatus membranes, resulting in a cell in which the vast majority of Golgi proteins are found in the ER. What inferences can be made from this observation regarding roles of coat proteins other than promoting vesicle formation? Predict what type of mutation in Arf1 might have the same effect as treating cells with BFA.

4. Microinjection of an antibody known as EAGE, which reacts with the "hinge" region of the β subunit of COPI, causes accumulation of Golgi enzymes in transport vesicles and inhibits anterograde transport of newly synthesized vesicles from the ER to the plasma membrane. What effect does the antibody have on COPI activity? Explain the results.

5. Specificity in fusion between vesicles involves two discrete and sequential processes. Describe the first of the two processes and its regulation by GTPase switch proteins. What effect on the size of early endosomes might result from overexpression of a mutant form of Rab5 that is stuck in the GTP-bound state?

6. *Sec18* is a yeast gene that encodes NSF. It is a class C mutant in the yeast secretory pathway. What is the mechanistic role of NSF in membrane trafficking? As indicated by its class C phenotype, why does an NSF mutation produce accumulation of vesicles at what appears to be only one stage of the secretory pathway?

7. What feature of procollagen synthesis provided early evidence for the Golgi cisternal maturation model?

8. Sorting signals that cause retrograde transport of a protein in the secretory pathway are sometimes known as retrieval sequences. List the two known examples of retrieval sequences for soluble and membrane proteins of the ER. How does the presence of a retrieval sequence on a soluble ER protein result in its retrieval from the *cis*-Golgi complex? Describe how the concept of a retrieval sequence is essential to the cisternal-maturation model.

9. Clathrin adapter protein (AP) complexes bind directly to the cytosolic face of membrane proteins and also interact with clathrin. What are the four known adapter protein complexes? What observation regarding AP3 suggests that clathrin is an accessory protein to a core coat composed of adapter proteins?

10. I-cell disease is a classic example of an inherited human defect in protein targeting that affects an entire class of proteins, soluble enzymes of the lysosome. What is the molecular defect in I-cell disease? Why does it affect the targeting of an entire class of proteins? What other types of mutations might produce the same phenotype?

11. The TGN, *trans*-Golgi network, is the site of multiple sorting processes as proteins and lipids exit the Golgi complex. Compare and contrast the sorting of proteins to lysosomes

versus the packaging of proteins into regulated secretory granules such as those containing insulin. Compare and contrast the sorting of proteins to the basolateral versus apical cell surfaces in MDCK cells versus hepatocytes.

12. What does the budding of influenza virus and vesicular stomatitis virus (VSV) from polarized MDCK cells reveal about the sorting of newly synthesized cell plasma membrane proteins to the apical or basolateral domains? Now consider the following result: A peptide with a sequence identical to that of the VSV G protein cytoplasmic domain inhibits targeting of the G protein to the basolateral surface and has no effect on HA targeting to the apical membrane, but a peptide in which the single tyrosine residue is mutated to an alanine has no effect on G protein basolateral targeting. What does this tell you about the sorting process?

13. Describe how pH plays a key role in regulating the interaction between mannose 6-phosphate and the mannose 6-phosphate receptor. Why does elevating endosomal pH lead to the secretion of newly synthesized lysosomal enzymes into the extracellular medium?

14. What mechanistic features are shared by (a) the formation of multivesicular endosomes by budding into the interior of the endosome and (b) the outward budding of HIV virus at the cell surface? You wish to design a peptide inhibitor/competitor of HIV budding and decide to mimic in a synthetic peptide a portion of the HIV Gag protein. Which portion of the HIV Gag protein would be a logical choice? What normal cellular process might this inhibitor block?

15. The phagocytic and autophagic pathways serve two fundamental roles, but both deliver their vesicles to the lysosome. What are the fundamental differences between the two pathways? Describe the three basic steps in the formation and fusion of autophagic vesicles.

16. Compare and contrast the location and pH sensitivity of receptor-ligand interaction in the LDL and transferrin receptor-mediated endocytosis (RME) pathways.

17. What do LDL receptor (LDLR) cytoplasmic domain mutations that cause familial hypercholesterolemia reveal about the receptor-mediated endocytosis (RME) pathway?

Analyze the Data

1. In order to examine the specificity of membrane fusion conferred by specific v-SNAREs and t-SNAREs, researchers reconstituted liposomes (artificial lipid membranes) with specific t-SNARE complexes or with v-SNAREs (see McNew et al., 2000, *Nature* 407:153–159). To measure fusion, the v-SNARE liposomes also contained a fluorescent lipid at a relatively high concentration such that its fluorescence is quenched. (Quenching is reduced fluorescence relative to that expected. In this case, quenching occurs because the fluorescent lipids are too concentrated and interfere with each other's ability to become excited.) On fusion of these liposomes with those lacking the fluorescent lipid, the fluorescent lipids are diluted, and quenching is alleviated. Three sets of liposomes were pre-

pared using yeast t-SNARE complexes: those containing plasma membrane t-SNAREs, Golgi t-SNAREs, or vacuolar t-SNAREs. Each of these was mixed with fluorescent liposomes containing one of three different yeast v-SNAREs. The following data were obtained.

- What can be deduced from these data about the specificity of membrane fusion events?
- Where might you expect to find v-SNAREs 1, 2, and 3 in yeast?
- What kind of experiment could be designed to determine where in the secretory pathway a given v-SNARE is required in vivo?
- The cytoplasmic domain of v-SNARE 2 has been expressed and purified from *E. coli*. Various amounts of this domain are incubated either with the Golgi t-SNARE liposomes or with v-SNARE 2 liposomes. The liposomes are then washed free of unbound protein. The various liposomes are then mixed, as indicated below, and the fluorescence of each sample is measured 1 hour after mixing. How can the data be explained? What would you predict the outcome to be if yeast were to overexpress the cytoplasmic domain of v-SNARE 2?

2. You have genetically engineered green fluorescent protein (GFP) containing a KDEL sequence. When the construct is transfected into normal human fibroblasts and examined using fluorescence microscopy, the fluorescence appears throughout the cytoplasm, as drawn below.

a. How would you explain this pattern given that KDEL is supposed to be an ER-specific sorting sequence?

b. To analyze the results further, fractions of different organelles and the cytoplasm were collected from cells expressing this KDEL-containing GFP construct and then examined on Western blots using antibodies against GFP (27 kDa) and protein disulfide isomerase (PDI), a resident-rough ER (RER) protein of approximately 55 kDa.

The blot confirms the presence of GFP exclusively in the cytoplasm, and as expected a PDI signal in the RER fraction. How would you explain the PDI band, albeit weak, in the Golgi fraction? Given the function of PDI proteins, what would you expect if both alleles of a PDI gene were knocked out in mice?

c. The antibodies used above do not detect any signals in the nuclear fraction, which indicates their specificity or the fact that no proteins were isolated and loaded in the nuclear fraction lane. What antibody could be used to show there were nuclear proteins present in this sample?

3. A child appears to be suffering from I-cell disease, but when a sample of his proteins (lane 3* below), isolated from

skin fibroblasts, is compared to protein samples from fibroblasts of his healthy parents (lanes 1 and 2) and siblings (lanes 4–6) using Western blot analysis and antibodies against *N*-acetylglucosamine phosphotransferase (~145 kDa) and actin (loading control, ~43 kDa), the following is seen:

In a second set of experiments, *N*-acetylglucosamine phosphotransferase was isolated from cells from the afflicted child and from his healthy parents, and used in an assay with ^{32}P to measure enzyme activity and the production of mannose 6-phosphate. The assay yielded the following results:

a. Using fibroblasts cultured from the child, design an experiment using the *N*-acetylglucosamine phosphotransferase antibody and fluorescence microscopy and draw the results that could explain why the child presents symptoms similar to I-cell disease.

b. Given the results from these three different experiments, how would you explain the I-cell symptoms seen in the child and what experiment would you propose to test your hypothesis?

c. A laser scanning confocal micrograph of MDCK cells labeled with an antibody against the mannose 6-phosphate receptor shows the following:

How do you explain the labeling on the apical and basolateral surfaces, for a receptor whose function is to target enzymes from the *trans*-Golgi network (TGN) to the lysosome? Likewise, what explains the labeling seen at the RER?

Following a Protein Out of the Cell

J. Jamieson and G. Palade, 1966, *Proc. Natl. Acad. Sci. USA* 55(2):424–431

The advent of electron microscopy allowed researchers to see the cell and its structures at an unprecedented level of detail. George Palade utilized this tool not only to look at the fine details of the cell but also to analyze the process of secretion. By combining electron microscopy with pulse-chase experiments, Palade uncovered the path proteins follow to leave the cell.

Background

In addition to synthesizing proteins to carry out cellular functions, many cells must also produce and secrete additional proteins that perform their duties outside the cell. Cell biologists, including Palade, wondered how secreted proteins make their passage from the inside to the outside of the cell. Early experiments suggesting that proteins destined for secretion are synthesized in a particular intracellular location and then follow a pathway to the cell surface employed methods to disrupt cells synthesizing a particular secreted protein and to separate their various organelles by centrifugation. These cell-fractionation studies showed that secreted proteins can be found in membrane-bounded vesicles derived from the endoplasmic reticulum (ER), where they are synthesized, and within zymogen granules, from which they are eventually released from the cell. Unfortunately, results from these studies were hard to interpret due to difficulties in obtaining clean separation of all of the different organelles that contain secretory proteins. To further clarify the pathway, Palade turned to a newly developed technique, high-resolution autoradiography, that allowed him to detect the position of radioactively labeled proteins in thin cell sections that had been prepared for electron microscopy of intracellular organelles. His work led to the seminal finding that secreted proteins travel within vesicles

from the ER to the Golgi complex and then to the plasma membrane.

The Experiment

Palade wanted to identify which cell structures and organelles participate in protein secretion. To study such a complex process, he carefully chose an appropriate model system for his studies, the pancreatic exocrine cell, which is responsible for producing and secreting large amounts of digestive enzymes. Because these cells have the unusual property of expressing only secretory proteins, a general label for newly synthesized protein, such as radioactively labeled leucine, will only be incorporated into protein molecules that are following the secretory pathway.

Palade first examined the protein secretion pathway *in vivo* by injecting live guinea pigs with [^3H]-leucine, which was incorporated into newly made proteins, thereby radioactively labeling them. At time points from 4 minutes to 15 hours, the animals were sacrificed, and the pancreatic tissue was fixed. By subjecting the specimens to autoradiography and viewing them in an electron microscope, Palade could trace where the labeled proteins were in cells at various times. As expected, the radioactivity localized in vesicles at the ER at time points immediately following the [^3H]-leucine injection and at the plasma membrane at the later time points. The surprise came in the middle time points. Rather than traveling straight from the ER to the plasma membrane, the radioactively labeled proteins appeared to stop off at the Golgi complex in the middle of their journey. In addition, there never was a time point where the radioactively labeled proteins were not confined to vesicles.

The observation that the Golgi complex was involved in protein secretion was both surprising and intriguing. To thoroughly address the role

of this organelle in protein secretion, Palade turned to *in vitro* pulse-chase experiments, which permitted more precise monitoring of the fate of labeled proteins. In this labeling technique, cells are exposed to radiolabeled precursor, in this case [^3H]-leucine, for a short period known as the *pulse*. The radioactive precursor is then replaced with its nonlabeled form for a subsequent *chase* period. Proteins synthesized during the pulse period will be labeled and detected by autoradiography, whereas those synthesized during the chase period, which are nonlabeled, will not be detected. Palade began by cutting guinea pig pancreas into thick slices, which were then incubated for 3 minutes in media containing [^3H]-leucine. At the end of the pulse, he added excess unlabeled leucine. The tissue slices were then either fixed for autoradiography or used for cell fractionation. To ensure that his results were an accurate reflection of protein secretion *in vivo*, Palade meticulously characterized the system. Once convinced that his *in vitro* system accurately mimicked protein secretion *in vivo*, he proceeded to the critical experiment. He pulse-labeled tissue slices with [^3H]-leucine for 3 minutes, then chased the label for 7, 17, 37, 57, and 117 minutes with unlabeled leucine. Radioactivity, again confined in vesicles, began at the ER, then traveled in vesicles to the Golgi complex and remained in the vesicles as they passed through the Golgi and onto the plasma membrane (see Figure 1). As the vesicles traveled farther along the pathway, they became more densely packed with radioactive protein. From his remarkable series of autoradiograms at different chase times, Palade concluded that secreted proteins travel in vesicles from the ER to the Golgi and onto the plasma membrane and that throughout this process, they remain in vesicles and do not mix with the rest of the cell.

FIGURE 1 The synthesis and movement of guinea pig pancreatic secretory proteins as revealed by electron microscope autoradiography. After a period of labeling with [^3H]-leucine, the tissue is fixed, sectioned for electron microscopy, and subjected to autoradiography. The radioactive decay of [^3H] in newly synthesized proteins produces autoradiographic grains in an emulsion placed over the cell section (which appear in the micrograph as dense, wormlike granules) that mark the position of newly synthesized proteins. (a) At the end of a 3-minute labeling period autoradiographic grains are over the rough ER. (b) Following a 7-minute chase period with unlabeled leucine, most of the labeled proteins have moved to the Golgi vesicles. (c) After a 37-minute chase, most of the proteins are over immature secretory vesicles. (d) After a 117-minute chase, the majority of the proteins are over mature zymogen granules. [Courtesy of J. Jamieson and G. Palade.]

Discussion

Palade's experiments gave biologists the first clear look at the stages of the secretory pathway. His studies on pancreatic exocrine cells yielded two fundamental observations. First, that secreted proteins pass through the Golgi complex on their way out of the cell. This was the first function assigned to the Golgi complex. Second, that secreted proteins never mix with cellular proteins in the cytosol; they are segregated into vesicles

throughout the pathway. These findings were predicated from two important aspects of the experimental design. Palade's careful use of electron microscopy and autoradiography allowed him to look at the fine details of the pathway. Of equal importance was the choice of a cell type devoted to secretion, the pancreatic exocrine cell, as a model system. In a different cell type, significant amounts of nonsecreted proteins would have also been produced

during the labeling, obscuring the fate of secretory proteins in particular.

Palade's work set the stage for more detailed studies. Once the secretory pathway was clearly described, entire fields of research were opened up to investigation of the synthesis and movement of both secreted and membrane proteins. For this groundbreaking work, Palade was awarded the Nobel Prize for Physiology and Medicine in 1974.

The mouse retina contains photoreceptors (purple) that sense light using G protein–coupled receptors and four other types of neurons stained yellow, green, pink, and blue, which connect the photoreceptor cells to the brain. [Rachel Wong, University of Washington]

SIGNAL TRANSDUCTION AND G PROTEIN– COUPLED RECEPTORS

No cell lives in isolation. Cellular communication is a fundamental property of all cells and shapes the development and function of every living organism. Even single-celled eukaryotic microorganisms, such as yeasts, slime molds, and protozoans, communicate through extracellular signals: secreted molecules called **pheromones** coordinate the aggregation of free-living cells for sexual mating or differentiation under certain environmental conditions. More important in plants and animals are **hormones** and other extracellular signaling molecules that function *within* an organism to control a variety of processes, including the metabolism of sugars, fats, and amino acids; the growth and differentiation of tissues; the synthesis and secretion of proteins; and the composition of intracellular and extracellular fluids. Many types of cells also respond to signals from the external environment, including light, oxygen, odorants, and tastants in food.

In any system, for a signal to have an effect on a target, it has to be received. In cells, a signal produces a specific response only in target cells with **receptors** for that signal. For

some receptors, this signal is a physical stimulus such as light, touch, or heat. For others, it is a chemical molecule. Many types of chemicals are used as signals: small molecules (e.g., amino acid or lipid derivatives, acetylcholine), gases (nitric oxide), peptides (e.g., ACTH and vasopressin), soluble proteins (e.g., insulin and growth hormone), and proteins that are tethered to the surface of a cell or bound to the extracellular matrix. Many of these extracellular signaling molecules are synthesized and released by specialized signaling cells within multicellular organisms. Most receptors bind a single molecule or a group of closely related molecules.

Some signaling molecules, especially hydrophobic molecules such as steroids, retinoids, and thyroxine, spontaneously diffuse through the plasma membrane and bind to intracellular receptors; signaling from such intracellular receptors is discussed in detail in Chapter 7.

Most extracellular signaling molecules, however, are too large and too hydrophilic to penetrate through the plasma membrane. How, then, can they affect intracellular processes?

FIGURE 15-1 Overview of signaling by cell-surface receptors.

Communication by extracellular signals usually involves the following steps: synthesis of the signaling molecule by the signaling cell and its incorporation into small intracellular vesicles (step 1), its release into the extracellular space by exocytosis (step 2), and transport of the signal to the target cell (step 3). Binding of the signaling molecule to a specific cell-surface receptor protein triggers a conformational change in the receptor, thus activating it (step 4). The activated receptor then activates one or more downstream signal transduction proteins or small-molecule second messengers (step 5), eventually leading to activation of one or more effector proteins (step 6). The end result of a signaling cascade can be either a short-term change in cellular function, metabolism, or movement (step 7a) or a long-term change in gene expression or development (step 7b). Termination or down-modulation of the cellular response is caused by negative feedback from intracellular signaling molecules (step 8) and by removal of the extracellular signal (step 9).

These signaling molecules bind to cell-surface receptors that are integral membrane proteins embedded in the plasma membrane. Cell-surface receptors generally consist of three discrete domains, or segments: an extracellular domain facing the extracellular fluid, a membrane-spanning (transmembrane) domain that spans the plasma membrane, and the intracellular domain segment facing the cytosol. The signaling molecule acts as a **ligand**, which binds to a structurally complementary site on the extracellular or the membrane-spanning domains of the receptor. Binding of the ligand to its site on the receptor induces a conformational change in the receptor that is transmitted through the membrane-spanning domain to the cytosolic domain, resulting in binding to and subsequent activation or inhibition of other proteins in the cytosol or attached to the plasma membrane. In many cases, these activated proteins catalyze the synthesis of certain small molecules or change the concentration of an intracellular ion such as Ca^{2+} . These intracellular proteins or small molecule **second messengers** then carry the signal to one or more effector proteins. The overall process of converting extracellular signals into intracellular responses, as well as the individual steps in this process, is termed **signal transduction** (Figure 15-1).

In eukaryotes, there are about a dozen classes of cell-surface receptors, which activate several types of intracellular signal transduction pathways. Our knowledge of signal transduction has advanced greatly in recent years, in large measure because these receptors and pathways are highly conserved and function in essentially the same way in organisms as diverse as worms, flies, mice, and humans. Genetic studies combined with biochemical analyses have enabled researchers to trace many entire signaling pathways from binding of ligand to final cellular response.

Perhaps the most numerous class of receptors—found in organisms from yeasts to humans—are **G protein-coupled receptors (GPCRs)**. As their name implies, G protein-coupled receptors consist of an integral membrane receptor protein coupled to an intracellular G protein that transmits signals to the interior of the cell. The human genome encodes about

900 G protein-coupled receptors, including receptors in the visual, olfactory (smell), and gustatory (taste) systems, many neurotransmitter receptors, and most of the receptors for hormones that control carbohydrate, amino acid, and fat metabolism and even behavior. Signal transduction through GPCRs usually induces short-term changes in cell function, such as a change in metabolism or movement. In contrast, activation of other cell-surface receptors primarily alters a cell's pattern of gene expression, leading to cell differentiation or division and other long-term consequences. These latter receptors and the intracellular signaling pathways they activate are explored in Chapter 16.

In this chapter, we first review some general principles of signal transduction, such as the molecular basis for ligand-receptor binding, and certain evolutionarily conserved components of signal transduction pathways. Next we describe how cell-surface receptors and signal transduction proteins are identified and characterized biochemically. We then turn to an in-depth discussion of G protein-coupled receptors, focusing first on their structure and mechanism of action and then on the signaling pathways activated by them. We show how these pathways affect many aspects of cell function, including glucose metabolism, muscle contraction, perception of light, and gene expression.

15.1 Signal Transduction: From Extracellular Signal to Cellular Response

As shown in Figure 15-1, signal transduction begins when extracellular signaling molecules bind to cell-surface receptors. Binding of signaling molecules to their receptors induces two major types of cellular responses: (1) changes in the activity or function of specific enzymes and other proteins that preexist in the cell and (2) changes in the amounts of specific proteins produced by a cell, most commonly by modification of **transcription factors** that stimulate or repress gene expression (see Figure 15-1, steps 7a and 7b). In general, the first type of response occurs more rapidly than the second. Transcription factors activated in the cytosol by these pathways move into the nucleus, where they stimulate (or occasionally repress) transcription of specific target genes.

The connection between an activated receptor and a cellular response is not direct and generally involves several intermediate proteins or small molecules. Collectively, this chain of intermediates is called a *signal transduction pathway* because it transduces, or converts, information from one form into another as a signal is relayed from a receptor to its targets. Some signal transduction pathways contain just two or three intermediates; others can involve over a dozen. Regardless, most pathways contain members of certain classes of signal transduction proteins that have been highly conserved throughout evolution.

In this section, we provide an overview of the major steps in signal transduction, starting with the signaling molecules themselves. We explore the molecular basis for ligand-receptor binding and the chain of events initiated in the target cell by binding of the signal to its receptor, focusing on a few components that are central to many signal transduction pathways.

Signaling Molecules Can Act Locally or at a Distance

Cells respond to many different types of signals—some originating from outside the organism, some internally generated. Those that are generated internally can be described by how they reach their target. Some signaling molecules are transported long distances by the blood; others have more local effects. In animals, signaling by extracellular molecules can be classified into three types—endocrine, paracrine, or autocrine—based on the distance over which the signal acts (Figure 15-2a–c). In addition, certain membrane-bound proteins on one cell can directly signal an adjacent cell.

In **endocrine signaling**, the signaling molecules are synthesized and secreted by signaling cells (for example, those found in endocrine glands), transported through the circulatory system of the organism, and finally act on target cells distant from their site of synthesis. The term *hormone* generally refers to signaling molecules that mediate endocrine signaling. Insulin secreted by the pancreas and epinephrine secreted by the adrenal glands are examples of hormones that travel through the blood and thus mediate endocrine signaling.

In **paracrine signaling**, the signaling molecules released by a cell affect only those target cells in close proximity. A nerve cell releasing a neurotransmitter (e.g., acetylcholine) that acts on an adjacent nerve cell or on a muscle cell (inducing or inhibiting muscle contraction) is an example of paracrine signaling. In addition to neurotransmitters, many protein **growth factors** regulating development in multicellular organisms act at short range. Some of these growth-factor proteins bind tightly to components of the extracellular matrix

(a) Endocrine signaling

(d) Signaling by plasma-membrane-attached proteins

FIGURE 15-2 Types of extracellular signaling. (a–c) Cell-to-cell signaling by extracellular chemicals occurs over distances from a few micrometers in autocrine and paracrine signaling to several meters in endocrine signaling. (d) Proteins attached to the plasma membrane of one cell can interact directly with cell-surface receptors on adjacent cells.

and are unable to signal to adjacent cells; subsequent degradation of these matrix components, triggered by injury or infection, will release the active growth factor and enable it to signal. Many developmentally important signaling proteins diffuse away from the signaling cell, forming a concentration gradient and inducing different cellular responses depending on the concentration of the signaling protein.

In autocrine signaling, cells respond to substances that they themselves release. Some growth factors act in this fashion, and cultured cells often secrete growth factors that stimulate their own growth and proliferation. This type of signaling is particularly characteristic of tumor cells, many of which overproduce and release growth factors that stimulate inappropriate, unregulated self-proliferation, a process that may lead to formation of a tumor.

Integral membrane proteins located on the cell surface also play an important role in signaling (Figure 15-2d). In some cases, such membrane-bound signals on one cell bind receptors on the surface of an adjacent target cell, triggering its differentiation. In other cases, proteolytic cleavage of a membrane-bound signaling protein releases the extracellular segment, which functions as a soluble signaling molecule.

Some signaling molecules can act at both short and long ranges. For example, epinephrine (also known as adrenaline) functions as a systemic hormone (endocrine signaling) and as a neurotransmitter (paracrine signaling). Another example is epidermal growth factor (EGF), which is synthesized as an integral plasma membrane protein. Membrane-bound EGF

can bind to receptors on an adjacent cell. In addition, cleavage by an extracellular protease releases a soluble form of EGF, which can signal in either an autocrine or a paracrine manner.

Binding of Signaling Molecules Activates Receptors on Target Cells

Receptor proteins for all hydrophilic extracellular small molecules and protein signaling molecules are located on the surface of the target cell. The signaling molecule, or ligand, binds to a site on the extracellular domain of the receptor with high specificity and affinity. Each receptor generally binds only a single signaling molecule or a group of structurally very closely related molecules. The *binding specificity* of a receptor refers to its ability to bind or not bind closely related substances.

Ligand binding depends on weak, multiple noncovalent forces (i.e., ionic, van der Waals, and hydrophobic interactions) and **molecular complementarity** between the interacting surfaces of a receptor and ligand (see Figure 2-12). For example, the growth hormone receptor (Figure 15-3) binds to growth hormone but not to other hormones with very similar, though not identical, structures. Similarly, acetylcholine receptors bind only this small molecule and not others that differ only slightly in chemical structure, while the insulin receptor binds insulin and related hormones called insulin-like growth factors 1 and 2 (IGF-1 and IGF-2), but no other hormones.

Binding of ligand to receptor causes a conformational change in the receptor that initiates a sequence of reactions

EXPERIMENTAL FIGURE 15-3 Growth hormone binds to its receptor through molecular complementarity. (a) As determined from the three-dimensional structure of the growth hormone–growth hormone receptor complex, 28 amino acids in the hormone are at the binding interface with one receptor. To determine which amino acids are important in ligand–receptor binding, researchers mutated each of these amino acids one at a time, to alanine, and measured the effect on receptor binding. From this study, it was found that only eight amino acids on growth hormone (pink) contribute 85 percent of the energy that is responsible for tight receptor binding; these amino acids are distant from each other in the primary sequence but adjacent in the

folded protein. Similar studies showed that two tryptophan residues (blue) in the receptor contribute most of the energy responsible for tight binding of growth hormone, although other amino acids at the interface with the hormone (yellow) are also important. (b) Binding of growth hormone to one receptor molecule is followed by (c) binding of a second receptor (purple) to the opposing side of the hormone; this involves the same set of yellow and blue amino acids on the receptor but different residues on the hormone. As we see in the next chapter, such hormone-induced receptor dimerization is a common mechanism for activation of receptors for protein hormones. [After B. Cunningham and J. Wells, 1993, *J. Mol. Biol.* **234**:554, and T. Clackson and J. Wells, 1995, *Science* **267**:383.]

leading to a specific response inside the cell. Organisms have evolved to be able to use a single ligand to stimulate different cells to respond in distinct ways. For example, different cell types may have different sets of receptors for the same ligand, each of which induces a different intracellular signal response pathway. Alternatively, the same receptor can be found on various cell types in an organism, but binding of a particular ligand to the receptor triggers a different response in each type of cell, given the unique complement of proteins expressed by the cell. In these ways, the same ligand can induce different cells to respond in a variety of ways. This is what's known as the *effector specificity* of the receptor-ligand complex.

For instance, the surfaces of skeletal muscle cells, heart muscle cells, and the pancreatic acinar cells that produce hydrolytic digestive enzymes each have different types of receptors for acetylcholine. In a skeletal muscle cell, release of acetylcholine from a motor neuron innervating the cell triggers muscle contraction by activating an acetylcholine-gated ion channel. In heart muscle, the release of acetylcholine by certain neurons activates a G protein-coupled receptor and slows the rate of contraction and thus the heart rate. Acetylcholine stimulation of pancreatic acinar cells triggers a rise in cytosolic $[Ca^{2+}]$ that induces exocytosis of the digestive enzymes stored in secretory granules to facilitate digestion of a meal. Thus formation of different acetylcholine-receptor complexes in different cell types leads to different cellular responses.

Protein Kinases and Phosphatases Are Employed in Virtually All Signaling Pathways

Activation of virtually all cell-surface receptors leads directly or indirectly to changes in protein phosphorylation through the activation of protein **kinases**, which add phosphate groups to specific residues of specific target proteins. Some receptors activate protein **phosphatases**, which remove phosphate groups from specific residues on target proteins. Phosphatases act in concert with kinases to switch the function of various proteins on or off (Figure 15-4).

At last count, the human genome encodes about 600 protein kinases and 100 different phosphatases. In general, each protein kinase phosphorylates specific amino acid residues in a set of target, or substrate, proteins whose patterns of expression generally differ in different cell types. Animal cells contain two types of protein kinases: those that add phosphate to the hydroxyl group on tyrosine residues and those that add phosphate to the hydroxyl group on serine or threonine (or both) residues. All kinases also bind to specific amino acid sequences surrounding the phosphorylated residue, and thus one can look at amino acid sequences surrounding tyrosine, serine, and threonine residues in a protein and make a good guess as to which kinases might phosphorylate this residue.

In some signaling pathways, the receptor itself possesses intrinsic kinase activity or the receptor is tightly bound to a cytosolic kinase. Figure 15-5 illustrates a simple signal transduction pathway involving one kinase tightly bound to a receptor and one predominant target protein. In the absence of a bound ligand the kinase is held in the inactive state. Ligand binding triggers a conformational change in the receptor,

FIGURE 15-4 Regulation of protein activity by a kinase/phosphatase switch. The cyclic phosphorylation and dephosphorylation of a protein is a common cellular mechanism for regulating protein activity. In this example, the target, or substrate, protein is inactive (light green) when not phosphorylated and active (dark green) when phosphorylated; some proteins have the opposite pattern. Both the protein kinase and the phosphatase act only on specific target proteins, and their activities are usually highly regulated.

leading to activation of the appended kinase. The kinase then phosphorylates the monomeric, inactive form of a specific transcription factor, leading to its dimerization and movement from the cytosol into the nucleus, where it activates transcription of target genes. A phosphatase in the nucleus subsequently removes the phosphate group from the transcription factor, causing it to form two inactive monomers and then move back into the cytosol, where it can be reactivated by a receptor-associated kinase.

As this example illustrates, the activity of all protein kinases is opposed by the activity of protein phosphatases, some of which are themselves regulated by extracellular signals. Thus the activity of a protein in a cell can be a complex function of the activities of the usually multiple kinases and phosphatases that act on it, either directly or indirectly through phosphorylation of another protein. Several examples of this phenomenon occur in regulation of the cell cycle and are described in Chapter 19.

Many proteins are substrates for multiple kinases, each of which phosphorylates different amino acids. Each phosphorylation event can modify the activity of a particular target protein in different ways, some activating its function, others inhibiting it. An example we encounter later is glycogen phosphorylase kinase, a key regulatory enzyme in glucose metabolism. In many cases, addition of a phosphate group to an amino acid creates a binding surface that allows a second protein to bind; in the following chapter we will encounter many examples of such kinase-driven assembly of multiprotein complexes.

Commonly the catalytic activity of a protein kinase itself is modulated by phosphorylation by other kinases, by the

FIGURE 15-5 A simple signal transduction pathway involving one kinase and one target protein. The receptor is tightly bound to a protein kinase that, in the absence of a bound ligand, is held in the inactive state. Ligand binding triggers a conformational change in the receptor, leading to activation of the appended kinase (1). The kinase then phosphorylates the monomeric, inactive form of a specific transcription factor (2), leading to its dimerization (3) and movement from the cytosol into the nucleus (4), where it activates transcription of target genes. A phosphatase in the nucleus will remove the phosphate group from the transcription factor (5), causing it to form the inactive monomer and then move back into the cytosol (6).

binding of other proteins to it, and by changes in the levels of various small intracellular signaling molecules and metabolites. The resulting cascades of kinase activity are a common feature of many signaling pathways.

GTP-Binding Proteins Are Frequently Used in Signal Transduction as On/Off Switches

Many signal transduction pathways utilize intracellular "switch" proteins that turn downstream proteins on or off. The most important group of intracellular switch proteins is the GTPase superfamily. All the GTPase switch proteins exist in two forms (Figure 15-6): (1) an active ("on") form with bound GTP (guanosine triphosphate) that modulates the activity of specific target proteins and (2) an inactive ("off") form with bound GDP (guanosine diphosphate).

Conversion of the inactive to active state is triggered by a signal (e.g., a hormone binding to a receptor) and is mediated by a *guanine nucleotide exchange factor* (GEF), which causes release of GDP from the switch protein. Subsequent binding of GTP, favored by its high intracellular concentration relative to its binding affinity, induces a conformational change to the active form. The principal conformational changes involve two highly conserved segments of the protein, termed switch I and switch II, that allow the protein to bind to and activate other downstream signaling proteins (Figure 15-7). Conversion of the active form back to the inactive state is

mediated by a GTPase, which slowly hydrolyzes the bound GTP to GDP and P_i , thus altering the conformation of the switch I and switch II segments so that they are unable to bind to the effector protein. The GTPase can be an intrinsic part of the G protein or a separate protein.

The rate of GTP hydrolysis regulates the length of time the switch protein remains in the active conformation and is

FIGURE 15-6 GTPase switch proteins cycle between active and inactive forms. The switch protein is active when it has bound GTP and inactive when it has bound GDP. Conversion of the active into the inactive form by hydrolysis of the bound GTP is accelerated by GAPs (GTPase-accelerating proteins) and other proteins. Reactivation is promoted by GEFs (guanine nucleotide exchange factors) that catalyze the dissociation of the bound GDP and its replacement by GTP.

FIGURE 15-7 Switching mechanism of G proteins. The ability of a G protein to interact with other proteins and thus transduce a signal differs in the GTP-bound “on” state and GDP-bound “off” state. (a) In the active “on” state, two domains, termed switch I (green) and switch II (blue), are bound to the terminal gamma phosphate of GTP through interactions with the backbone amide groups of a conserved threonine and glycine residue. When bound to GTP in this way, the two switch domains are in a conformation such that they can bind to and thus activate specific downstream effector proteins. (b) Release of the gamma phosphate by GTPase-catalyzed hydrolysis causes switch I and switch II to relax into a different conformation, the inactive “off” state; in this state they are unable to bind to effector proteins. The ribbon models shown here represent both conformations of Ras, a monomeric G protein. A similar spring-loaded mechanism switches the alpha subunit in trimeric G proteins between the active and inactive conformations by movement of three switch segments. [Adapted from I. Vetter and A. Wittinghofer, 2001, *Science* **294**:1299.]

able to signal its downstream target proteins: the slower the rate of GTP hydrolysis, the longer the protein remains in the active state. The rate of GTP hydrolysis is often modulated by other proteins. For instance, both *GTPase-activating proteins* (GAP) and *regulator of G protein signaling* (RGS) *proteins* accelerate GTP hydrolysis. Many regulators of G protein activity are themselves controlled by extracellular signals.

Two large classes of GTPase switch proteins are used in signaling. **Trimeric (large) G proteins** directly bind to and are activated by certain cell-surface receptors. As we will see in Section 15.3, G protein-coupled receptors function as guanine nucleotide-exchange factors (GEFs)—triggering release of GDP and binding of GTP, thus activating the G protein. **Monomeric (small) G proteins**, such as Ras and various Ras-like proteins, are not bound to receptors but play crucial roles in many pathways that regulate cell division and cell motility, as is evidenced by the fact that mutations in genes encoding these G proteins frequently lead to cancer. Other members of both GTPase classes, by switching between GTP-bound “on” and GDP-bound “off” forms, function in protein synthesis, the transport of proteins between the nucleus and the cytoplasm, the formation of coated vesicles and their fusion with target membranes, and rearrangements of the actin cytoskeleton.

Intracellular “Second Messengers” Transmit and Amplify Signals from Many Receptors

The binding of ligands (“first messengers”) to many cell-surface receptors leads to a short-lived increase (or decrease) in the concentration of certain low-molecular-weight intracellular

signaling molecules termed **second messengers**. These, in turn, bind to other proteins, modifying their activity.

One second messenger used in virtually all metazoan cells is Ca^{2+} ions. We noted in Chapter 11 that the concentration of free Ca^{2+} in the cytosol is kept very low ($<10^{-7}$ M) by ATP-powered pumps that continually transport Ca^{2+} out of the cell or into the endoplasmic reticulum (ER). The cytosolic Ca^{2+} level can increase from 10- to 100-fold by a signal-induced release of Ca^{2+} from ER stores or by its import through calcium channels from the extracellular environment; this change can be detected by fluorescent dyes introduced into the cell (see Figure 9-11). In muscle, a signal-induced rise in cytosolic Ca^{2+} triggers contraction (see Figure 17-35). In endocrine cells, a similar increase in Ca^{2+} induces exocytosis of secretory vesicles containing hormones, which are thus released into the circulation. In nerve cells, an increase in cytosolic Ca^{2+} leads to the exocytosis of neurotransmitter-containing vesicles (see Chapter 22). In all cells, this rise in cytosolic Ca^{2+} is sensed by Ca^{2+} -binding proteins, particularly those of the *EF hand family*, such as *calmodulin*, all of which contain the helix-loop-helix motif (see Figure 3-9b). The binding of Ca^{2+} to calmodulin and other EF hand proteins causes a conformational change that permits the protein to bind various target proteins, thereby switching their activities on or off (see Figure 3-31).

Another nearly universal second messenger is cyclic AMP (cAMP). In many eukaryotic cells, a rise in cAMP triggers activation of a particular protein kinase, protein kinase A, that in turn phosphorylates specific target proteins to induce specific changes in cell metabolism. In some cells, cAMP

FIGURE 15-8 Four common intracellular second messengers. The major direct effect or effects of each compound are indicated below its

structural formula. Calcium ions (Ca²⁺) and several membrane-bound phosphatidylinositol derivatives also act as second messengers.

regulates the activity of certain ion channels. The structures of cAMP and three other common second messengers are shown in Figure 15-8. Later in this chapter, we examine the specific roles of second messengers in signaling pathways activated by various G protein-coupled receptors.

Because second messengers such as Ca²⁺ and cAMP diffuse through the cytosol much faster than do proteins, they are employed in pathways where the downstream target is located in an intracellular organelle (such as a secretory vesicle or the nucleus) distant from the plasma membrane receptor where the messenger is generated.

Another advantage of second messengers is that they facilitate *amplification* of an extracellular signal. Activation of a *single* cell-surface receptor molecule can result in an increase in perhaps thousands of cAMP molecules or Ca²⁺ ions in the cytosol. Each of these, in turn, by activating its target protein affects the activity of multiple downstream proteins. In many signal transduction pathways, amplification is necessary because cell surface receptors are typically low-abundance proteins, present in only a thousand or so copies per cell. Yet the cellular responses induced by the binding of a relatively small

number of hormones to the available receptors often require production of tens or hundreds of thousands of activated effector molecules per cell. In the case of G protein-coupled hormone receptors, *signal amplification* is possible in part because a single receptor can activate multiple G proteins, each of which in turn activates an effector protein. For example, a single epinephrine-GPCR complex causes activation of up to 100 adenylyl cyclase molecules, each of which in turn catalyzes synthesis of many cAMP molecules during the time it remains in the active state. Two cAMP molecules activate one molecule of protein kinase A that in turn phosphorylates and activates multiple target product molecules (Figure 15-9). Later in this chapter, we see how this amplification cascade allows blood levels of epinephrine as low as 10⁻¹⁰ M to stimulate glycogenolysis (conversion of glycogen to glucose) by the liver and release of glucose into the blood.

FIGURE 15-9 Amplification of an extracellular signal. In this example, binding of a single epinephrine molecule to one G protein-coupled receptor molecule induces activation of several molecules of adenylyl cyclase, the enzyme that catalyzes the synthesis of cyclic AMP, and each of these enzyme synthesizes a large number of cAMP molecules, the first level of amplification. Two molecules of cAMP activate one molecule of protein kinase A (PKA), but each activated PKA phosphorylates and activates multiple target proteins. This second level of amplification may involve several sequential reactions in which the product of one reaction activates the enzyme catalyzing the next reaction. The more steps in such a cascade, the greater the signal amplification possible.

KEY CONCEPTS of Section 15.1

Signal Transduction: From Extracellular Signal to Cellular Response

- All cells communicate through extracellular signals. In unicellular organisms, extracellular signaling molecules regulate interactions between individuals, while in multicellular organisms, they regulate physiology and development.
- External signals include membrane-anchored and secreted proteins or peptides (e.g., vasopressin and insulin), small hydrophobic molecules (e.g., steroid hormones and thyroxine), small hydrophilic molecules (e.g., epinephrine), gases (e.g., O₂, nitric oxide), and physical stimuli (e.g., light).
- Binding of extracellular signaling molecules to cell-surface receptors triggers a conformational change in the receptor, which in turn leads to activation of intracellular signal transduction pathways that ultimately modulate cellular metabolism, function, or gene expression (see Figure 15-1).
- Signals from one cell act on distant cells in endocrine signaling, on nearby cells in paracrine signaling, or on the signaling cell itself in autocrine signaling (see Figure 15-2).
- Protein phosphorylation and de-phosphorylation, catalyzed by protein kinases and phosphatases, are employed in virtually all signaling pathways. The activities of kinases and phosphatases are highly regulated by many receptors and signal transduction proteins (see Figures 15-4 and 15-5).
- GTP-binding proteins of the GTPase superfamily act as switches regulating many signal transduction pathways (see Figures 15-6 and 15-7).
- Ca²⁺, cAMP, and other nonprotein, low-molecular-weight intracellular molecules (see Figure 15-8) act as “second messengers,” relaying and often amplifying the signal of the “first messenger,” that is, the ligand. Binding of ligand to cell-surface receptors often results in a rapid increase (or, occasionally, decrease) in the intracellular concentration of these ions or molecules.

15.2 Studying Cell-Surface Receptors and Signal Transduction Proteins

The response of a cell to an external signal depends on the cell's complement of receptors that recognize the signal and the signal transduction pathways activated by those receptors. In this section, we explore the biochemical basis for the specificity of receptor-ligand binding, as well as the ability of different concentrations of ligand to activate a pathway. We also examine experimental techniques used to characterize receptor proteins. Many of these methods are also applicable to receptors that mediate endocytosis (see Chapter 14) or cell adhesion (see Chapter 20). We conclude the section with a discussion of techniques commonly used to measure the

activity of signal transduction components, such as kinases and GTP-binding “switch” proteins.

The Dissociation Constant Is a Measure of the Affinity of a Receptor for Its Ligand

Ligand binding to a receptor usually can be viewed as a simple reversible reaction, where the receptor is represented as R, the ligand as L, and the receptor-ligand complex as RL:

k_{off} is the rate constant for dissociation of a ligand from its receptor, and k_{on} is the rate constant for formation of a receptor-ligand complex from free ligand and receptor.

At equilibrium, the rate of formation of the receptor-ligand complex is equal to the rate of its dissociation and can be described by the simple equilibrium-binding equation

$$K_d = \frac{[R][L]}{[RL]} \quad (15-2)$$

where [R] and [L] are the concentrations of free receptor (that is, receptor without bound ligand) and ligand, respectively, at equilibrium, and [RL] is the concentration of the receptor-ligand complex. K_d , the **dissociation constant**, is a measure of the *affinity* (or tightness of binding) of the receptor for its ligand (see also Chapter 2). For a simple binding reaction, $K_d = k_{\text{off}}/k_{\text{on}}$. The *lower* k_{off} is relative to k_{on} , the more *stable* the RL complex—the tighter the binding—and thus the *lower* the value of K_d . Another way of seeing this key point is that K_d equals the concentration of ligand at which half of the receptors have a ligand bound when the system is at equilibrium; at this ligand concentration $[R] = [RL]$ and thus, from Equation 15-2, $K_d = [L]$. The lower the K_d , the lower the ligand concentration required to bind 50 percent of the cell-surface receptors. The K_d for a binding reaction here is essentially equivalent to the Michaelis constant K_m , which reflects the affinity of an enzyme for its substrate (see Chapter 3). Like all equilibrium constants, however, the value of K_d does not depend on the *absolute* values of k_{off} and k_{on} , only on their ratio. In the next section, we learn how K_d values are experimentally determined.

Hormone receptors are characterized by their high affinity and specificity for their ligands. Because of their high affinity and great specificity for their target hormone, the extracellular, ligand-binding domains of cell surface receptors can be converted into powerful drugs. Consider the hormone tumor necrosis factor alpha (TNF α), which is secreted by a number of immune system cells. TNF α induces inflammation by recruiting various immune cells to a site of injury or infection; abnormal levels of TNF α cause the excessive inflammation seen in patients with autoimmune diseases

such as the blistering skin disease psoriasis or the joint disease rheumatoid arthritis. These diseases are being treated with a chimeric “fusion” protein, generated by recombinant DNA, that contains the extracellular domain of a TNF α receptor fused to the constant (Fc) region of a human immunoglobulin (see Figures 3-19 and 23-8). The drug binds tightly to free TNF α and prevents it from binding to its cell-surface receptors and causing inflammation; the fused Fc domain causes the protein to be stable when injected into the body. ■

Binding Assays Are Used to Detect Receptors and Determine Their Affinity and Specificity for Ligands

Usually receptors are detected and measured by their ability to bind radioactive or fluorescent ligands to intact cells or to cell fragments. Figure 15-10 illustrates such a *binding assay* for interaction of the red-cell-forming hormone erythropoietin (Epo) with Epo receptors that are expressed by recombinant DNA in a line of cultured cells. The amounts of radioactive Epo bound to its receptor on growing cells (vertical axis) were measured as a function of increasing concentration of ^{125}I -labeled Epo added to the extracellular fluid (horizontal axis). Both the number of ligand-binding sites per cell and the K_d value are easily determined from the specific binding curve (curve C). Assuming each receptor binds just one ligand molecule, the total number of ligand-binding sites on a cell equals the number of active receptors per cell. In the example shown in Figure 15-10, the value of K_d is about 1.1×10^{-10} M, or 0.1 nM. In other words, an Epo concentration of 1.1×10^{-10} M in the extracellular fluid is required for 50 percent of a cell's Epo receptors to have a bound Epo.

Direct binding assays like the one in Figure 15-10 are feasible with receptors that have a high affinity for their ligands, such as the erythropoietin receptor and the insulin receptor on liver cells ($K_d = 1.4 \times 10^{-10}$ M). However, many ligands, such as epinephrine and other catecholamines, bind to their receptors with much lower affinity. If the K_d for binding is greater than $\sim 1 \times 10^{-7}$ M, a case when the rate constant k_{off} is relatively large compared to k_{on} , then it is likely that during the seconds to minutes required to measure the amount of bound ligand, some of the receptor-bound ligand will dissociate and thus the observed binding values will be systematically too low.

One way to measure relatively weak binding of a ligand to its receptor is in a *competition assay* with another ligand that binds to the same receptor with high affinity (low K_d value). In this type of assay, increasing amounts of an unlabeled, low-affinity ligand (the competitor) are added to a cell sample with a constant amount of the radiolabeled, high-affinity ligand (Figure 15-11). Binding of unlabeled competitor to the receptor blocks binding of the radioactive ligand to the receptor. The concentration dependence of this competition can be used together with the K_d value of the radioactive ligand to calculate the inhibitory constant, K_i , which is very close to the K_d value for binding of the competitor to the receptor. It is possible to accurately measure the amount

EXPERIMENTAL FIGURE 15-10 Binding assays can determine the K_d and the number of receptors per cell. Shown here are data for erythropoietin-specific receptors on the surface of a cultured mouse cell line that expresses a recombinant human erythropoietin (Epo) receptor compared to control cells that do not normally express the receptor. A suspension of cells is incubated for 1 hour at 4 °C with increasing concentrations of ^{125}I -labeled Epo; the low temperature is used to prevent endocytosis of the cell-surface receptors. The cells are separated from unbound ^{125}I Epo, usually by centrifugation, and the amount of radioactivity bound to them is measured. The total binding curve A represents Epo specifically bound to high-affinity receptors as well as Epo nonspecifically bound with low affinity to other molecules on the cell surface. The contribution of nonspecific binding to total binding is determined by repeating the binding assay with the control cell line, where Epo binds only to nonspecific sites, yielding curve B. The specific binding curve C is calculated as the difference between curves A and B. As determined by the maximum of the specific binding curve C, the number of specific Epo-binding sites (surface receptors) per cell is about 2200 (3.7×10^{-15} moles $\times 6.02 \times 10^{23}$ molecules/mole/10⁶ cells = 2227 molecules/cell). The K_d is the concentration of Epo required to bind to 50 percent of the surface Epo receptors (in this case about 1050 receptors/cell). Thus the K_d is about 1.1×10^{-10} M, or 0.1 nM. [Courtesy Alec Gross; after A. Gross and H. Lodish, 2006, *J. Biol. Chem.* 281:2024.]

of the high-affinity ligand bound in this assay because little dissociates during the experimental manipulations required for the measurement (relatively low k_{off}).

 Competitive binding is often used to study synthetic analogs of natural hormones that activate or inhibit receptors. These analogs, which are widely used in research on cell-surface receptors and as drugs, fall into two classes: **agonists**, which mimic the function of a natural hormone by binding to its receptor and inducing the normal response, and **antagonists**, which bind to the receptor but induce no response. By occupying ligand-binding sites on a receptor, an antagonist can block binding of the natural hormone (or agonist) and thus reduce the usual physiological activity of the hormone. In other words, antagonists inhibit receptor signaling. ■

EXPERIMENTAL FIGURE 15-11 For low-affinity ligands, binding can be detected in competition assays. In this example, the synthetic ligand alprenolol, which binds with high affinity to the epinephrine receptor on liver cells ($K_d \sim 3 \times 10^{-9}$ M), is used to detect the binding of two low-affinity ligands, the natural hormone epinephrine (EP) and a synthetic ligand called isoproterenol (IP). Assays are performed as described in Figure 15-10 but in reactions containing a constant amount of [3 H] alprenolol and increasing amounts of unlabeled epinephrine or isoproterenol. At each competitor concentration, the amount of bound labeled alprenolol is determined. In a plot of

the inhibition of [3 H] alprenolol binding versus epinephrine or isoproterenol concentration, such as shown here, the concentration of the competitor that inhibits alprenolol binding by 50 percent approximates the K_d value for competitor binding. Note that the concentrations of competitors are plotted on a logarithmic scale. The K_d for binding of epinephrine to its receptor on liver cells is only $\sim 5 \times 10^{-5}$ M and would not be measurable by a direct binding assay with [3 H] epinephrine. The K_d for binding of isoproterenol, which induces the normal cellular response, is more than tenfold lower.

Consider for instance the drug isoproterenol, used to treat asthma. Isoproterenol is made by the chemical addition of two methyl groups to epinephrine (see Figure 15-11, right). Isoproterenol, an agonist of the epinephrine-responsive G protein-coupled receptors on bronchial smooth muscle cells, binds about tenfold more strongly (tenfold lower K_d) than does epinephrine (see Figure 15-11, left). Because activation of these receptors promotes relaxation of bronchial smooth muscle and thus opening of the air passages in the lungs, isoproterenol is used in treating bronchial asthma, chronic bronchitis, and emphysema. In contrast, activation of a different type of epinephrine-responsive G protein-coupled receptors on cardiac muscle cells (called β -adrenergic receptors) increases the heart contraction rate. Antagonists of this receptor, such as alprenolol and related compounds, are referred to as *beta-blockers*; such antagonists are used to slow heart contractions in the treatment of cardiac arrhythmias and angina.

Maximal Cellular Response to a Signaling Molecule Usually Does Not Require Activation of All Receptors

All signaling systems evolved such that a rise in the level of extracellular signaling molecules induces a proportional response in the responding cell. For this to happen, the binding affinity (K_d value) of a cell-surface receptor for a signaling molecule must be greater than the normal (unstimulated)

level of that molecule in the extracellular fluids or blood. We can see this principle in practice by comparing the levels of insulin present in the body and the K_d for binding of insulin to its receptor on liver cells, 1.4×10^{-10} M. Suppose, for instance, that the normal concentration of insulin in the blood is 5×10^{-12} M. By substituting this value and the insulin K_d into Equation 15-2, we can calculate the fraction of insulin receptors with bound insulin

$$\frac{[RL]}{[RL] + [R]}$$

at equilibrium as 0.0344; that is, about 3 percent of the total insulin receptors will be bound with insulin. If the insulin concentration rises fivefold to 2.5×10^{-11} M, the number of receptor-hormone complexes will rise proportionately, almost fivefold, so that about 15 percent of the total receptors will have bound insulin. If the extent of the induced cellular response parallels the number of insulin-receptor complexes, [RL], as is often the case, then the cellular responses also will increase by about fivefold.

On the other hand, suppose that the normal concentration of insulin in the blood were the same as the K_d value of 1.4×10^{-10} M; in this case, 50 percent of the total receptors would have a bound insulin. A fivefold increase in the insulin concentration to 7×10^{-10} M would result in 83 percent of all insulin receptors having insulin bound (a 66 percent increase). Thus, in order for a rise in hormone concentration

EXPERIMENTAL FIGURE 15-12 The maximal physiological response to an external signal occurs when only a fraction of the receptors are occupied by ligand. For signaling pathways that exhibit this behavior, plots of the extent of ligand binding to the receptor and of physiological response at different ligand concentrations differ. In the example shown here, 50 percent of the maximal physiological response is induced at a ligand concentration at which only 18 percent of the receptors are occupied. Likewise, 80 percent of the maximal response is induced when the ligand concentration equals the K_d value, at which 50 percent of the receptors are occupied.

to cause a proportional increase in the fraction of receptors with bound ligand, the normal concentration of the hormone must be well below the K_d value.

In general, the maximal cellular response to a particular ligand is induced when much less than 100 percent of its receptors are bound to the ligand. This phenomenon can be revealed by determining the extent of the response and of receptor-ligand binding at different concentrations of ligand (Figure 15-12). For example, a typical red blood (erythroid) progenitor cell has ~ 1000 surface receptors for erythropoietin, the protein hormone that induces these cells to proliferate and differentiate into red blood cells. Because only 100 of these receptors need to bind erythropoietin to induce division of a progenitor cell, the ligand concentration needed to induce 50 percent of the maximal cellular response is proportionally lower than the K_d value for binding. In such cases, a plot of the percentage of maximal binding versus ligand concentration differs from a plot of the percentage of maximal cellular response versus ligand concentration.

Sensitivity of a Cell to External Signals Is Determined by the Number of Surface Receptors and Their Affinity for Ligand

Because the cellular response to a particular signaling molecule depends on the *number* of receptor-ligand complexes, the fewer receptors present on the surface of a cell, the less *sensitive* the cell is to that ligand. As a consequence, a higher ligand concentration is necessary to induce the physiological response than would be the case if more receptors were present.

To illustrate the important relationship between receptor number and ligand sensitivity, let's extend our example of a

typical erythroid progenitor cell. The K_d for binding of erythropoietin (Epo) to its receptor is about 10^{-10} M. As we noted above, only 10 percent of the ~ 1000 erythropoietin receptors on the surface of a cell must be bound to ligand to induce the maximal cellular response. We can determine the ligand concentration, $[L]$, needed to induce the maximal response by rewriting Equation 15-2 as follows:

$$[L] = \frac{K_d}{\frac{R_T}{[RL]} - 1} \quad (15-3)$$

where $R_T = [R] + [RL]$, the total number of receptors per cell. If the total number of Epo receptors per cell, R_T , is 1000, K_d is 10^{-10} M, and $[RL]$ is 100 (the number of Epo-occupied receptors needed to induce the maximal response), then an Epo concentration ($[L]$) of 1.1×10^{-11} M will elicit the maximal response. If the total number of Epo receptors (R_T) is reduced to 200 per cell, then a ninefold-higher Epo concentration (10^{-10} M) is required to occupy 100 receptors and induce the maximal response. Clearly, therefore, a cell's sensitivity to a signaling molecule is heavily influenced by the number of receptors for that ligand that are present as well as the K_d .

 Epithelial growth factor (EGF), as its name implies, stimulates the proliferation of many types of epithelial cells, including those that line the ducts of the mammary gland. In about 25 percent of breast cancers, the tumor cells produce elevated levels of one particular EGF receptor called HER2. The overproduction of HER2 makes the cells hypersensitive to ambient levels of EGF that normally are too low to stimulate cell proliferation; as a consequence, growth of these tumor cells is inappropriately stimulated by EGF. We will see in Chapter 16 that an understanding of the role of HER2 in certain breast cancers led to development of monoclonal antibodies that bind HER2 and thereby block signaling by EGF; these antibodies have proved useful in treatment of these breast cancer patients. ■

The HER2–breast cancer connection vividly demonstrates that regulation of the number of receptors for a given signaling molecule expressed by a cell plays a key role in directing physiological and developmental events. Such regulation can occur at the levels of transcription, translation, and post-translational processing or by controlling the rate of receptor degradation. Alternatively, endocytosis of receptors on the cell surface can sufficiently reduce the number present such that the cellular response is terminated. As we discuss in later sections, other mechanisms can reduce a receptor's affinity for ligand and so reduce the cell's response to a given concentration of ligand. Thus reduction in a cell's sensitivity to a particular ligand, called *desensitization*, can result from various mechanisms and is critical to the ability of cells to respond appropriately to external signals.

Receptors Can Be Purified by Affinity Techniques

In order to fully understand how receptors function, it is necessary to purify them and analyze their biochemical properties. Determining their molecular structures with and without a bound ligand, for instance, can elucidate the conformational changes that occur on ligand binding that activate downstream signal transduction proteins. But this can be challenging. A “typical” mammalian cell has 1000 to 50,000 copies of a single type of cell-surface receptor. This may seem like a large number, but when you consider that this same cell contains $\sim 10^{10}$ total protein molecules and $\sim 10^6$ proteins in the plasma membrane alone, you realize that these receptors constitute only 0.1 to 5 percent of plasma-membrane proteins. This low abundance complicates the isolation and purification of cell-surface receptors. Purification of receptors is also difficult because these integral membrane proteins first must be solubilized from the membrane with a non-ionic detergent (see Figure 10-23) and then separated from other cellular proteins.

As we saw with the Epo receptor discussed earlier, recombinant DNA techniques can be used to generate cells that express large amounts of these proteins. But even when recombinant DNA techniques are used to generate cells that express receptors in large amounts, special techniques are necessary to isolate and purify them from other membrane proteins. One technique often used in purifying cell-surface receptors that retain their ligand-binding ability when solubilized by detergents is similar to *affinity chromatography* using antibodies (see Figure 3-38c). To purify a receptor by this technique, a ligand for the receptor of interest, rather than an antibody, is chemically linked to the beads used to form a column. A crude, detergent-solubilized preparation of membrane proteins is passed through the column; only the receptor binds, while other proteins are washed away. Passage of an excess of the soluble ligand through the column causes the bound receptor to be displaced from the beads and eluted from the column. In some cases, a receptor can be purified as much as 100,000-fold in a single affinity-chromatographic step.

Immunoprecipitation Assays and Affinity Techniques Can Be Used to Study the Activity of Signal Transduction Proteins

Following ligand binding, receptors activate one or more signal transduction proteins that, in turn, can affect the activity of multiple effector proteins (see Figure 15-1); to understand a signaling cascade requires the researcher to be able to quantify the activity of these signal transduction proteins. Kinases and GTP-binding proteins are found in many signaling cascades, and in this section we describe several assays used for measuring their activities.

Immunoprecipitation of Kinases Kinases function in virtually all signaling pathways, and typical mammalian cells contain a hundred or more different kinases, each of which

is highly regulated and can phosphorylate many target proteins. Immunoprecipitation assays are frequently used to measure the activity of a particular kinase in a cell extract. In one version of the method, an antibody specific for the desired kinase is first reacted with small beads coated with Protein A; this causes the antibody to bind to the beads via its Fc segment (see Figure 9-29). The beads are then mixed with a preparation of cell cytosol or nucleus, then recovered by centrifugation and washed extensively with a salt solution to remove weakly bound proteins that are unlikely to be binding specifically to the antibody. Thus only cell proteins that specifically bind to the antibody—the kinase itself and proteins tightly bound to the kinase—are present on the beads. The beads are then incubated in a buffered solution with a substrate protein and γ -[^{32}P] ATP, where only the γ phosphate is labeled. The amount of [^{32}P] transferred to the substrate protein is a measure of kinase activity and can be quantified either by polyacrylamide gel electrophoresis followed by autoradiography (see Figure 3-36) or by immunoprecipitation with an antibody specific for the substrate followed by counting the radioactivity in the immunoprecipitate. By comparing extracts from cells before and after ligand addition, for example, one can readily determine whether or not a particular kinase is activated in the signal transduction pathway triggered by that ligand.

We noted that many proteins can be phosphorylated by several different kinases, usually on different serine, threonine, or tyrosine residues. Thus it is important to measure the extent of phosphorylation of a single amino acid side chain in a specific protein, say before and after hormone stimulation. Antibodies play a crucial role in detecting such phosphorylation events. To generate an antibody that can recognize a specific phosphorylated amino acid in a specific protein, one first chemically synthesizes an approximately 15 amino acid peptide that has the amino acid sequence surrounding the phosphorylated amino acid of the specific protein but where a phosphate group has been chemically linked to the desired serine, threonine, or tyrosine. After coupling this peptide to an adjuvant to increase its immunogenicity, it is used to generate a set of monoclonal antibodies (see Figure 9-6). One then selects a particular monoclonal antibody that reacts only with the phosphorylated, but not the nonphosphorylated peptide; such an antibody generally will bind to the parent protein only when this specific amino acid is phosphorylated. This specificity is possible because the antibody binds simultaneously to the phosphorylated amino acid and to side chains of adjacent amino acids. As an example of the use of such antibodies, Figure 15-13 shows that three signal transduction proteins in red-cell progenitors become phosphorylated on specific amino acid residues within 10 minutes of stimulation by varying concentrations of the hormone erythropoietin; phosphorylation increases with Epo concentration and is the first step in triggering the differentiation of these cells into red blood cells.

Pulldown Assays of GTP-Binding Proteins We’ve seen that the GTPase superfamily of intracellular-switch proteins cycle

EXPERIMENTAL FIGURE 15-13 Activation of three signal transduction proteins by phosphorylation. Mouse erythrocyte progenitor cells were treated for 10 min with different concentrations of the hormone erythropoietin (Epo). Extracts of the cell were analyzed by Western blotting with three different antibodies specific for the phosphorylated forms of three signal transduction proteins and three that recognize a nonphosphorylated segment of amino acids in the same protein. The data show that with increasing concentration of Epo, the three proteins become phosphorylated. Treatment with 1 unit Epo per ml is sufficient to maximally phosphorylate and thus activate all three pathways. Stat 5 = transcription factor phosphorylated on tyrosine 694; Akt = kinase phosphorylated on serine 473; p42/p44 = p42/p44 MAP kinase phosphorylated on threonine 202 and tyrosine 204. between an active (“on”) form with bound GTP that modulates the activity of specific target proteins and an inactive (“off”) form with bound GDP. The principal assay for measuring activation of this class of proteins takes advantage of the fact that each such protein has one or more targets to

EXPERIMENTAL FIGURE 15-14 A pull-down assay shows that the small GTP-binding protein Rac1 is activated by platelet-derived growth factor (PDGF). Like other small GTPases, Rac1 regulates molecular events by cycling between an inactive GDP-bound form and an active GTP-bound form. In its active (GTP-bound) state, Rac1 binds specifically to the p21-binding domain (PBD) of p21-activated protein kinase (PAK) to control downstream signaling cascades. (a) Assay principle: the Rac-binding PBD domain is generated by recombinant DNA techniques and attached to agarose beads, then mixed with cell extracts (step 1). The beads are recovered by centrifugation (step 2) and the amount of GTP-bound Rac1 is quantified by Western blotting using an anti-Rac1 antibody (step 3). (b) Western blot showing activation of Rac1 after treatment of hematopoietic stem cells for 1 min with the hormone platelet-derived growth factor (PDGF). A Western blot for actin serves as a control that the same amount of total protein is loaded on each lane of the gel. [(a) After Cell Biolabs Inc.; (b) from G. Ghiaur et al., 2006, *Blood* 108:2087–2094.]

which it binds only when it has a bound GTP; the target protein usually has a specific binding domain that binds to the switch segments of the GTP-binding protein. Pull-down assays used to quantify the activation of a specific GTP-binding protein are similar to immunoprecipitations except that the specific binding domain of the target protein is immobilized on small beads (Figure 15-14). The beads are mixed with a cell extract and then recovered by centrifugation; the amount of the GTP-binding protein on the beads is quantified by Western blotting. The example in Figure 15-14 shows that

(a) Assay Principle

(b) Western blot of hematopoietic stem cells before and after treatment with PDGF

the fraction of the small GTPase Rac1 that has a bound GTP increases markedly after stimulation by the hormone platelet-derived growth factor (PDGF), indicating that Rac1 is a signal transduction protein activated by the PDGF receptor.

KEY CONCEPTS of Section 15.2

Studying Cell-Surface Receptors and Signal Transduction Proteins

- The concentration of ligand at which half the ligand's receptors are occupied, the K_d , can be determined experimentally and is a measure of the affinity of the receptor for the ligand (see Figure 15-10).
- Because of receptors' high affinity for their target ligand, the extracellular domain of receptors can be used as a drug to reduce the level of free hormone.
- The maximal response of a cell to a particular ligand generally occurs at ligand concentrations at which less than 100 percent of its receptors are bound to ligand (see Figure 15-12).
- Affinity chromatography techniques can be used to purify receptors even when they are present in low abundance.
- Immunoprecipitation assays using antibodies specific for protein kinases can measure kinase activity. Immunoprecipitation assays using antibodies specific for phosphorylated peptides can measure phosphorylation of a specific amino acid on any desired protein within a cell (see Figure 15-13).
- Pull-down assays using the protein-binding domain of a target protein can be used to quantify activation of a GTP-binding protein within a cell (see Figure 15-14).

15.3 G Protein–Coupled Receptors: Structure and Mechanism

As noted above, perhaps the most numerous class of receptors are the G protein–coupled receptors (GPCRs). In humans, GPCRs are used to detect and respond to many different types of signals, including neurotransmitters, hormones involved in glycogen and fat metabolism, and even photons of light. All GPCR signal transduction pathways share the following common elements: (1) a receptor that contains seven membrane-spanning α helices; (2) a coupled trimeric G protein, which functions as a switch by cycling between active and inactive forms; (3) a membrane-bound effector protein; and (4) proteins that participate in feedback regulation and desensitization of the signaling pathway. A second messenger also occurs in many GPCR pathways. GPCR pathways usually have short-term effects in the cell by quickly modifying existing proteins, either enzymes or ion channels. Thus these pathways allow cells to respond rapidly to a variety of signals, whether they are environmental stimuli such as light or hormonal stimuli such as epinephrine.

In this section, we discuss the basic structure and mechanism of GPCRs and their associated trimeric G proteins. In Sections 15.4 through 15.6, we describe GPCR pathways that activate several different effector proteins.

All G Protein–Coupled Receptors Share the Same Basic Structure

All G protein–coupled receptors have the same orientation in the membrane and contain seven transmembrane α -helical regions (H1–H7), four extracellular segments (E1–E4), and four cytosolic segments (C1–C4) (Figure 15-15). Invariably the N-terminus is on the exoplasmic face and the C-terminus is on the cytosolic face of the plasma membrane. The carboxyl-terminal segment (C4), the C3 loop, and, in some receptors, also the C2 loop are involved in interactions with a coupled trimeric G protein. Many subfamilies of G protein–coupled receptors have been conserved through evolution; members of these subfamilies are especially similar in amino acid sequence and structure.

G protein–coupled receptors are stably anchored in the hydrophobic core of the plasma membrane by many hydrophobic amino acids on the outer surfaces of the seven membrane-spanning segments. One group of G protein–coupled receptors whose structure is known in molecular detail is the β -adrenergic receptors, which bind hormones such as epinephrine and norepinephrine (Figure 15-16). In these and many other receptors, segments of several membrane-embedded α helices and extracellular loops form the ligand binding site that is open to the exoplasmic surface. The antagonist cyanopindolol, shown in Figure 15-16, binds with a much higher affinity to the receptor than most agonists, and the receptor–ligand complex has been crystallized and its structure determined. Side chains of 15 amino acids located in four transmembrane α helices and extracellular loop 2 make

FIGURE 15-15 General structure of G protein–coupled receptors. All receptors of this type have the same orientation in the membrane and contain seven transmembrane α -helical regions (H1–H7), four extracellular segments (E1–E4), and four cytosolic segments (C1–C4). The carboxyl-terminal segment (C4), the C3 loop, and, in some receptors, also the C2 loop are involved in interactions with a coupled trimeric G protein.

FIGURE 15-16 Structure of the turkey β_1 -adrenergic receptor complexed with the antagonist cyanopindolol.

(a) Side view showing the approximate location of the membrane phospholipid bilayer. A ribbon representation of the receptor structure is in rainbow coloration (N-terminus, blue; C-terminus, red), with cyanopindolol as a gray space-filling model. The extracellular loop 2 (E2) and cytoplasmic loops 1 and 2 (C1, C2) are labeled. (b) View from external face showing a close-up of the ligand-binding pocket that is formed by amino acids in helices 3, 5, 6, and 7, as well as extracellular loop 2, located between helices 4 and 5. Cyanopindolol atoms are colored grey (carbon), blue (nitrogen), and red (oxygen). The ligand-binding pocket comprises 15 side chains from amino acid residues in four transmembrane α -helices and extracellular loop 2. As examples of specific binding interactions, the positively charged N atom in the amino group found both in cyanopindolol and in epinephrine forms an ionic bond with the carboxylate side chain of aspartate 121 (D^{121}) in helix 3 and the carboxylate of asparagine 329 (N^{329}) in helix 7. [From T. Wayne et al., 2008, *Nature* 454:486.]

noncovalent contacts with the ligand. The amino acids that form the interior of different G protein-coupled receptors are diverse, allowing different receptors to bind very different small molecules, whether they are hydrophilic such as epinephrine or hydrophobic such as many odorants.

While all G protein-coupled receptors share the same basic structure, different subtypes of GPCRs can bind the same hormone, with different cellular effects. To illustrate the versatility of these receptors, we will consider the set of G protein-coupled receptors for epinephrine found in different types of mammalian cells. The hormone **epinephrine** is particularly important in mediating the body's response to stress, also known as the fight-or-flight response. During moments of fear or heavy exercise, when tissues may have an increased need to catabolize glucose and fatty acids to produce ATP, epinephrine signals the rapid breakdown of glycogen to glucose in the liver and of triacylglycerols to fatty acids in adipose (fat) cells; within seconds these principal metabolic fuels are supplied to the blood. In mammals, the liberation of glucose and fatty acids is triggered by binding of epinephrine (or its derivative norepinephrine) to β -adrenergic receptors on the surface of hepatic (liver) and adipose cells.

Epinephrine has other bodily effects as well. Epinephrine bound to β -adrenergic receptors on heart muscle cells, for example, increases the contraction rate, which increases the blood supply to the tissues. In contrast, epinephrine stimulation of β -adrenergic receptors on smooth muscle cells of the intestine causes them to relax. Another type of epinephrine GPCR, the α -adrenergic receptor, is found on smooth muscle cells lining the blood vessels in the intestinal tract, skin, and kidneys. Binding of epinephrine to these receptors causes the arteries to constrict, cutting off circulation to these organs. These diverse effects of epinephrine help orchestrate integrated responses throughout the body all directed to a common end: supplying energy to major locomotor muscles, while at the same time diverting it from other organs not as crucial in executing a response to bodily stress.

Ligand-Activated G Protein–Coupled Receptors Catalyze Exchange of GTP for GDP on the α Subunit of a Trimeric G Protein

Trimeric G proteins contain three subunits designated α , β , and γ . Both the G_α and G_γ subunits are linked to the membrane by covalently attached lipids. The β and γ subunits are always bound together and are usually referred to as the $G_{\beta\gamma}$ subunit. In the resting state, when no ligand is bound to the receptor, the G_α subunit has a bound GDP and is complexed with $G_{\beta\gamma}$. Binding of a ligand (e.g., epinephrine) or an agonist (e.g., isoproterenol) to a G protein–coupled receptor changes the conformation of its cytosol-facing loops and

enables the receptor to bind to the G_α subunit (Figure 15-17, steps **1** and **2**). This binding releases the bound GDP; thus the activated ligand-bound receptor functions as a guanine nucleotide exchange factor (GEF) for the G_α subunit (step **3**). Next, GTP rapidly binds to the “empty” guanine nucleotide site in the G_α subunit, causing a change in the conformation of its switch segments (see Figure 15-7). These changes weaken the binding of G_α with both the receptor and the $G_{\beta\gamma}$ subunit (step **4**). In most cases, G_α •GTP, which remains anchored in the membrane, then interacts with and activates an effector protein, as depicted in Figure 15-17 (step **5**). In some cases, G_α •GTP inhibits the effector. Moreover, depending on the type of cell and G protein, the $G_{\beta\gamma}$ subunit, freed

OVERVIEW ANIMATION: Extracellular Signaling

FIGURE 15-17 General mechanism of the activation of effector proteins associated with G protein–coupled receptors. The G_α and $G_{\beta\gamma}$ subunits of trimeric G proteins are tethered to the membrane by covalently attached lipid molecules (wiggly black lines). Following ligand binding, exchange of GDP with GTP, and dissociation of the G protein subunits (steps **1**–**4**), the free G_α •GTP binds to and activates an effector protein (step **5**). Hydrolysis of GTP terminates signaling

and leads to reassembly of the trimeric G protein, returning the system to the resting state (step **6**). Binding of another ligand molecule causes repetition of the cycle. In some pathways, the effector protein is activated by the free $G_{\beta\gamma}$ subunit. The *s* in *trimeric G_s protein* stands for “stimulatory.” [After W. Oldham and H. Hamm, 2006, *Quart. Rev. Biophys.* 39:117.]

from its α subunit, will sometimes transduce a signal by interacting with an effector protein.

The active $G_{\alpha}\cdot GTP$ state is short-lived because the bound GTP is hydrolyzed to GDP in minutes, catalyzed by the intrinsic GTPase activity of the G_{α} subunit (see Figure 15-17, step 6). The conformation of the G_{α} thus switches back to the inactive $G_{\alpha}\cdot GDP$ state, blocking any further activation of effector proteins. The rate of GTP hydrolysis is sometimes further enhanced by binding of the $G_{\alpha}\cdot GTP$ complex to the effector; the effector thus functions as a GTPase-activating protein (GAP). This mechanism significantly reduces the duration of effector activation and avoids a cellular overreaction. In many cases, a second type of GAP protein called a regulator of G protein signaling (RGS) also accelerates GTP hydrolysis by the G_{α} subunit, further reducing the time during which the effector remains activated. The resulting $G_{\alpha}\cdot GDP$ quickly reassociates with $G_{\beta\gamma}$ and the complex becomes ready to interact with an activated receptor and start the process all over again. Thus the GPCR signal transduction system contains a built-in feedback mechanism that ensures the effector protein becomes activated only for a few seconds or minutes following receptor activation; continual activation of receptors via ligand binding together with subsequent activation of the corresponding G protein is essential for prolonged activation of the effector.

Early evidence supporting the model shown in Figure 15-17 came from studies with compounds called GTP analogs that are structurally similar to GTP and so can bind to G_{α} subunits

as well as GTP does but cannot be hydrolyzed by the intrinsic GTPase. In some of these compounds, the P-O-P phosphodiester linkage connecting the β and γ phosphates of GTP is replaced by a nonhydrolyzable P-CH₂-P or P-NH-P linkage. Addition of such a GTP analog to a plasma membrane preparation in the presence of an agonist for a particular receptor results in a much longer-lived activation of the G protein and its associated effector protein than occurs with GTP. In this experiment, once the nonhydrolyzable GTP analog is exchanged for GDP bound to G_{α} , it remains permanently bound to G_{α} . Because the $G_{\alpha}\cdot GTP$ -analog complex is as functional as the normal $G_{\alpha}\cdot GTP$ complex in activating the effector protein, the effector remains permanently active.

GPCR-mediated dissociation of trimeric G proteins can be detected in living cells. These studies have exploited the phenomenon of *fluorescence energy transfer*, which changes the wavelength of emitted fluorescence when two fluorescent proteins interact (see Figure 9-22). Figure 15-18 shows how this experimental approach has demonstrated the dissociation of the $G_{\alpha}\cdot G_{\beta\gamma}$ complex within a few seconds of ligand addition, providing further evidence for the model of G protein cycling. This general experimental approach can be used to follow the formation and dissociation of other protein-protein complexes in living cells.

For many years, it was impossible to determine the structure of the same GPCR in the active and inactive states. This has now been accomplished with the β -adrenergic receptor (as

PODCAST: Activation of G Proteins Measured by Fluorescence Resonance Energy Transfer (FRET)

EXPERIMENTAL FIGURE 15-18 Activation of G proteins occurs within seconds of ligand binding in amoeba cells. In the amoeba *Dictyostellium discoideum* cell, cAMP acts as an extracellular signaling molecule and binds to a G protein-coupled receptor; it is not a second messenger. Amoeba cells were transfected with genes encoding two fusion proteins: a G_{α} fused to cyan fluorescent protein (CFP), a mutant form of green fluorescent protein (GFP), and a G_{β} fused to another GFP variant, yellow fluorescent protein (YFP). CFP normally fluoresces 490-nm light; YFP, 527-nm light. (a) When CFP and YFP are nearby, as in the resting $G_{\alpha}\cdot G_{\beta\gamma}$ complex, fluorescence energy transfer can occur between CFP and YFP (left). As a result, irradiation of resting cells with 440-nm light (which directly excites CFP but not YFP) causes

emission of 527-nm (yellow) light, characteristic of YFP. However, if ligand binding leads to dissociation of the G_{α} and $G_{\beta\gamma}$ subunits, then fluorescence energy transfer cannot occur. In this case, irradiation of cells at 440 nm causes emission of 490-nm light (cyan) characteristic of CFP (right). (b) Plot of the emission of yellow light (527 nm) from a single transfected amoeba cell before and after addition of extracellular cyclic AMP (arrow), the ligand for the G protein-coupled receptor in these cells. The drop in yellow fluorescence, which results from the dissociation of the G_{α} -CFP fusion protein from the G_{β} -YFP fusion protein, occurs within seconds of cAMP addition. [Adapted from C. Janetopoulos et al., 2001, *Science* 291:2408.]

well as with rhodopsin, discussed in Section 15.4). The seven membrane-embedded α helices of the β -adrenergic receptor completely surround a central segment to which an agonist or antagonist is noncovalently bound (Figure 15-19). Binding of an agonist to the receptor induces a major conformational

FIGURE 15-19 Structure of the β -adrenergic receptor in the inactive and active states and with its associated trimeric G protein, $G_{\alpha s}$. (a) Comparison of the three-dimensional structures of the activated β -adrenergic receptor (gold) bound to a strong agonist and the inactive receptor (purple) bound to an antagonist. (b) View from the cytosolic surface. Note the major changes seen in the conformations of the intracellular domains of transmembrane helices 5 (TM5) and 6 (TM6). In the active state, TM5 is extended by two helical turns, whereas TM6 is moved outward by 1.4 nm. (c) The overall structure of the active receptor complex shows the adrenergic receptor (gold) bound to an agonist (black and red spheres) and engaged in extensive interactions with a segment of $G_{\alpha s}$ (purple). $G_{\alpha s}$ together with G_{β} (green) and G_{γ} (red) constitute the heterotrimeric G protein G_s . [After S. Rasmussen et al., 2011, *Nature* **476**:387–390.]

change (Figure 15-19a) in which there are substantial movements of transmembrane helices 5 and 6 and changes in the structure of the C3 loop; together these create a surface that can now bind to a segment of the $G_{\alpha s}$ subunit (Figure 15-19b).

X-ray crystallographic studies of the complex of activated receptor and G_s have also revealed how the subunits of a G protein interact with each other and provided clues about how binding of GTP leads to dissociation of the G_{α} from the $G_{\beta\gamma}$ subunit. As revealed in the structural model in Figure 15-19b, a large surface of $G_{\alpha}\cdot\text{GDP}$ interacts with the G_{β} subunit; part of this surface is located in the αN alpha helix in the N-terminal segment of $G_{\alpha}\cdot\text{GDP}$. Note that G_{α} directly contacts G_{β} but not G_{γ} . Binding of the N-terminal alpha-helical segments αN and $\alpha 5$ of the $G_{\alpha s}$ protein to transmembrane helices 5 and 6 of the activated receptor (Figure 15-19b) will, as with other G proteins, be followed by opening of the G_{α} subunit, eviction of the bound GDP, and its replacement with GTP; this is immediately followed by conformational changes within switches I and II that disrupt the molecular interactions between G_{α} and $G_{\beta\gamma}$, leading to their dissociation.

Different G Proteins Are Activated by Different GPCRs and In Turn Regulate Different Effector Proteins

All effector proteins in GPCR pathways are either membrane-bound ion channels or membrane-bound enzymes that catalyze formation of the second messengers shown in Figure 15-8. The variations on the theme of GPCR signaling that we examine in Sections 15.4 through 15.6 arise because multiple G proteins are encoded in eukaryotic genomes. At last count, humans have 21 different G_{α} subunits encoded by 16 genes, several of which undergo alternative splicing; six G_{β} subunits; and 12 G_{γ} subunits. So far as is known, the different $G_{\beta\gamma}$ subunits are essentially interchangeable in their functions, while the different G_{α} subunits afford the various G proteins their specificity. Thus we can refer to the entire three-subunit G protein by the name of its alpha subunit.

Table 15-1 summarizes the functions of the major classes of G proteins with different G_{α} subunits. For example, the different types of epinephrine receptors mentioned previously

TABLE 15-1 Major Classes of Mammalian Trimeric G Proteins and Their Effectors*

G _α Class	Associated Effector	2nd Messenger	Receptor Examples
G _{αs}	Adenylyl cyclase	cAMP (increased)	β-Adrenergic (epinephrine) receptor; receptors for glucagon, serotonin, vasopressin
G _{ai}	Adenylyl cyclase K ⁺ channel (G _{βγ} activates effector)	cAMP (decreased) Change in membrane potential	α ₂ -Adrenergic receptor Muscarinic acetylcholine receptor
G _{αolf}	Adenylyl cyclase	cAMP (increased)	Odorant receptors in nose
G _{αq}	Phospholipase C	IP ₃ , DAG (increased)	α ₁ -Adrenergic receptor
G _{α12}	Phospholipase C	IP ₃ , DAG (increased)	Acetylcholine receptor in endothelial cells
G _{αt}	cGMP phosphodiesterase	cGMP (decreased)	Rhodopsin (light receptor) in rod cells

*A given G_α subclass may be associated with more than one effector protein. To date, only one major G_{αs} has been identified, but multiple G_{αq} and G_{αi} proteins have been described. Effector proteins commonly are regulated by G_α but in some cases by G_{βγ} or the combined action of G_α and G_{βγ}. IP₃ = inositol 1,4,5-trisphosphate; DAG = 1,2-diacylglycerol.

SOURCES: See L. Birnbaumer, 1992, *Cell* 71:1069; Z. Farfel et al., 1999, *New Eng. J. Med.* 340:1012; and K. Pierce et al., 2002, *Nature Rev. Mol. Cell Biol.* 3:639.

are coupled to different G_α subunits that influence effector proteins differently and so have distinct effects on cell behavior in a target cell. Both subtypes of β-adrenergic receptors, termed β₁ and β₂, are coupled to a *stimulatory* G protein (G_s) whose alpha subunit (G_{αs}) activates a membrane-bound effector enzyme called **adenylyl cyclase**. Once activated, this enzyme catalyzes synthesis of the second messenger cAMP. In contrast, the α₂ subtype of β-adrenergic receptor is coupled to an *inhibitory* G protein (G_i) whose alpha subunit (G_{αi}) inhibits adenylyl cyclase, the same effector enzyme associated with β-adrenergic receptors. The G_{αq} subunit, which is coupled to the α₁-adrenergic receptor, activates a different effector enzyme, **phospholipase C**, which generates two other second messengers, DAG and IP₃ (see Figure 15-8). Examples of signaling pathways that use each of the G_α subunits listed in Table 15-1 are described in the following three sections.

Some bacterial toxins contain a subunit that penetrates the plasma membrane of target mammalian cells and in the cytosol catalyzes a chemical modification on G_α proteins that prevents hydrolysis of bound GTP to GDP. For example, toxins produced by the bacterium *Vibrio cholera*, which causes cholera, or certain strains of *E. coli*, modify the G_{αs} protein in intestinal epithelial cells. As a result, G_{αs} remains in the active state, continuously activating the effector adenylyl cyclase in the absence of hormonal stimulation. The resulting excessive rise in intracellular cAMP leads to the loss of electrolytes and water into the intestinal lumen, producing the watery diarrhea characteristic of infection by these bacteria. The toxin produced by *Bordetella pertussis*, a bacterium that commonly infects the respiratory tract and causes whooping cough, catalyzes a modification of G_{αi} that prevents release of bound GDP. As a result, G_{αi} is locked in the inactive state,

reducing the inhibition of adenylyl cyclase. The resulting increase in cAMP in epithelial cells of the airways promotes loss of fluids and electrolytes and mucus secretion. ■

KEY CONCEPTS of Section 15.3

G Protein–Coupled Receptors: Structure and Mechanism

- G protein–coupled receptors (GPCRs) are a large and diverse family with a common structure of seven membrane-spanning α helices and an internal ligand-binding pocket that is specific for ligands (see Figures 15-15 and 15-16).
- GPCRs can have a range of cellular effects depending on the subtype of receptor that binds ligand. The hormone epinephrine, for example, which mediates the fight-or-flight response, binds to multiple subtypes of GPCRs in multiple cell types, with varying physiological effects.
- GPCRs are coupled to trimeric G proteins, which contain three subunits designated α, β, and γ. The G_α subunit is a GTPase switch protein that alternates between an active (“on”) state with bound GTP and inactive (“off”) state with GDP. The “on” form separates from the β and γ subunits and activates a membrane-bound effector. The β and γ subunits remain bound together and only occasionally transduce signals (see Figure 15-17).
- Ligand binding causes a conformational change in certain membrane-spanning helices and intracellular loops of the GPCR, allowing it to bind to and function as a guanine nucleotide exchange factor (GEF) for its coupled G_α subunit,

catalyzing dissociation of GDP and allowing GTP to bind. The resulting change in conformation of switch regions in G_{α} causes it to dissociate from the $G_{\beta\gamma}$ subunit and the receptor and interact with an effector protein (see Figure 15-17).

- Fluorescence energy-transfer experiments demonstrate receptor-mediated dissociation of coupled G_{α} and $G_{\beta\gamma}$ subunits in living cells (see Figure 15-18).
- The effector proteins activated (or inactivated) by trimeric G proteins are either enzymes that form second messengers (e.g., adenylyl cyclase, phospholipase C) or ion channels (see Table 15-1). In each case, it is the G_{α} subunit that determines the function of the G protein and affords its specificity.

15.4 G Protein–Coupled Receptors That Regulate Ion Channels

One of the simplest cellular responses to a signal is the opening of ion channels essential for transmission of nerve impulses. Nerve impulses are essential to the sensory perception of environmental stimuli such as light and odors, to transmission of information to and from the brain, and to the stimulation of muscle movement. During transmission of nerve impulses, the opening and closing of ion channels causes changes in the membrane potential. Many neurotransmitter receptors are ligand-gated ion channels, which open in response to binding of a ligand. Such receptors include some types of glutamate, serotonin, and acetylcholine receptors, including the acetylcholine receptor found at nerve-muscle synapses. Ligand-gated ion channels that function as neurotransmitter receptors are covered in Chapter 22.

Many neurotransmitter receptors, however, are G protein–coupled receptors whose effector proteins are Na^{+} or K^{+} channels. Neurotransmitter binding to these receptors causes the associated ion channel to open or close, leading to changes in the membrane potential. Still other neurotransmitter receptors, as well as odorant receptors in the nose and photoreceptors in the eye, are G protein–coupled receptors that indirectly modulate the activity of ion channels via the action of second messengers. In this section, we consider two G protein–coupled receptors that illustrate the direct and indirect mechanisms for regulating ion channels: the muscarinic acetylcholine receptor of the heart and the light-activated rhodopsin protein in the eye.

Acetylcholine Receptors in the Heart Muscle Activate a G Protein That Opens K^{+} Channels

Muscarinic acetylcholine receptors are a type of GPCR found in cardiac muscle. When activated, these receptors *slow* the rate of heart muscle contraction. Because muscarine, an acetylcholine analog, also activates these receptors, they are termed “muscarinic.” This type of acetylcholine

FIGURE 15-20 Activation of the muscarinic acetylcholine receptor and its effector K^{+} channel in heart muscle. Binding of acetylcholine triggers activation of the $G_{\alpha i}$ subunit and its dissociation from the $G_{\beta\gamma}$ subunit in the usual way (see Figure 15-17). In this case, the released $G_{\beta\gamma}$ subunit (rather than $G_{\alpha i}$ •GTP) binds to and opens the associated effector protein, a K^{+} channel. The increase in K^{+} permeability hyperpolarizes the membrane, which reduces the frequency of heart muscle contraction. Though not shown here, activation is terminated when the GTP bound to $G_{\alpha i}$ is hydrolyzed (by a GAP enzyme that is an intrinsic part of the $G_{\alpha i}$ subunit) to GDP and $G_{\alpha i}$ •GDP recombines with $G_{\beta\gamma}$. [See K. Ho et al., 1993, *Nature* 362:31, and Y. Kubo et al., 1993, *Nature* 362:127.]

receptor is coupled to a $G_{\alpha i}$ subunit, and ligand binding leads to opening of associated K^{+} channels (the effector protein) in the plasma membrane (Figure 15-20). The subsequent efflux of K^{+} ions from the cytosol causes an increase in the magnitude of the usual inside-negative potential across the plasma membrane that lasts for several seconds. This state of the membrane, called **hyperpolarization**, reduces the frequency of muscle contraction. This effect can be shown experimentally by adding acetylcholine to isolated heart muscle cells and measuring the membrane potential using a microelectrode inserted into the cell (see Figure 11-19).

As shown in Figure 15-20, the signal from activated muscarinic acetylcholine receptors is transduced to the effector channel protein by the released $G_{\beta\gamma}$ subunit rather than by $G_{\alpha i}$ •GTP. That $G_{\beta\gamma}$ directly activates the K^{+} channel was demonstrated by patch-clamping experiments, which can measure ion flow through a single ion channel in a small patch of membrane (see Figure 11-22). When purified $G_{\beta\gamma}$ protein was added to the cytosolic face of a patch of heart muscle plasma membrane, K^{+} channels opened immediately, even in the absence of acetylcholine or other neurotransmitters—clearly indicating that it is the $G_{\beta\gamma}$ protein that is responsible for opening the effector K^{+} channels and not $G_{\alpha i}$ •GTP.

Light Activates G Protein–Coupled Rhodopsins in Rod Cells of the Eye

The human retina contains two types of photoreceptor cells, *rods* and *cones*, which are the primary recipients of visual stimulation. Cones are involved in color vision, while rods are stimulated by weak light such as moonlight over a range of wavelengths. The photoreceptor cells synapse on layer upon layer of interneurons that are innervated by different combinations of photoreceptor cells. All these signals are processed and interpreted by the part of the brain called the *visual cortex*.

Rod cells sense light with the aid of a light-sensitive GPCR known as *rhodopsin*. Rhodopsin consists of the protein opsin, which has the usual GPCR structure, covalently linked to a light-absorbing pigment called retinal. Rhodopsin, found only in rod cells, is localized to the thousand or so

flattened membrane disks that make up the outer segment of these rod-shaped cells (Figure 15-21). A human rod cell contains about 4×10^7 molecules of rhodopsin. The trimeric G protein coupled to rhodopsin, called *transducin* (G_t), contains a G_α unit referred to as $G_{\alpha t}$; like rhodopsin, $G_{\alpha t}$ is found only in rod cells.

Rhodopsin differs from other GPCRs in that binding of a ligand is not what activates the receptor. Rather, absorption of a photon of light by the bound retinal is the activating signal. On absorption of a photon, the retinal moiety of rhodopsin is immediately converted from the *cis* form (known as 11-*cis*-retinal) to the all-trans isomer, causing a conformational change in the opsin protein (Figure 15-22). This is equivalent to the activating conformational change that occurs on ligand binding by other G protein–coupled receptors; this conformational

FIGURE 15-21 Human rod cell. (a) Schematic diagram of an entire rod cell. At the synaptic body, the rod cell forms synapses with one or more interneurons. Rhodopsin, a light-sensitive G protein–coupled receptor, is located in the flattened membrane disks of the cell's outer segment. (b) Electron micrograph of the region of the rod cell indicated by the bracket in (a). This region includes the junction of the inner and outer segments. (Part (b) from R. G. Kessel and R. H. Kardon, 1979, *Tissues and Organs: A Text-Atlas of Scanning Electron Microscopy*, W. H. Freeman and Company, p. 91.)

FIGURE 15-22 The light-triggered step in vision. The light-absorbing pigment 11-*cis*-retinal is covalently bound to the amino group of a lysine residue in opsin, the protein part of rhodopsin. Absorption of light causes rapid photoisomerization of the bound *cis*-retinal to the all-*trans* isomer. This triggers a conformational change in the opsin protein, forming the unstable intermediate *meta*-rhodopsin II, or activated opsin (see Figure 15-23), which activates G_t proteins. Within seconds, all-*trans*-retinal dissociates from opsin and is converted by an enzyme back to the *cis* isomer, which then rebinds to another opsin molecule. [See J. Nathans, 1992, *Biochemistry* 31:4923.]

change allows rhodopsin to bind an adjacent $G_{\alpha t}$ subunit of the coupled G protein, triggering exchange of GTP for GDP. Activated rhodopsin, R^* , is unstable and spontaneously dissociates into its component parts, releasing the covalently attached opsin, which can no longer bind to a $G_{\alpha t}$ subunit and all-*trans*-retinal, thereby terminating visual signaling. In the dark, free all-*trans*-retinal is converted back to 11-*cis*-retinal, which can then rebind to opsin, re-forming rhodopsin.

Activation of Rhodopsin by Light Leads to Closing of cGMP-Gated Cation Channels

In the dark, the membrane potential of a rod cell is about -30 mV, considerably less than the resting potential (-60 to -90 mV) typical of neurons and other electrically active cells. This state of the membrane, called **depolarization**, causes rod cells in the dark to constantly secrete neurotransmitters, and thus the neurons with which they synapse are continually being stimulated. The depolarized state of the plasma

membrane of resting rod cells is due to the presence of a large number of open *nonselective* ion channels that admit Na^+ and Ca^{2+} ; recall from Chapter 11 that movement of positively charged ions such as Na^+ and Ca^{2+} from the outside of the cell to the inside will reduce the magnitude of the inside-negative membrane potential. Absorption of light by rhodopsin leads to closing of these channels, causing the membrane potential to become *more* inside negative.

The more photons absorbed by rhodopsin, the more channels are closed, the fewer Na^+ and Ca^{2+} ions cross the membrane from the outside, the more negative the membrane potential becomes, and the less neurotransmitter is released. The reduction in neurotransmitter release is transmitted to the brain by a series of neurons, where it is perceived as light.

Unlike the muscarinic acetylcholine receptor discussed earlier, G proteins activated by rhodopsin do not act directly on ion channels. The closing of cation channels in the rod-cell plasma membrane requires changes in the concentration of the second messenger cyclic GMP, or cGMP (see Figure 15-8). Rod cell outer segments contain an unusually high concentration (~ 0.07 mM) of cGMP, which is continuously formed from GTP in a reaction catalyzed by guanylyl cyclase. However, light absorption by rhodopsin induces activation of a *cGMP phosphodiesterase* (PDE), which hydrolyzes cGMP to 5'-GMP. As a result, the cGMP concentration decreases on illumination. The high level of cGMP present in the dark acts to keep *cGMP-gated cation channels* open; the light-induced decrease in cGMP leads to channel closing, membrane hyperpolarization, and reduced neurotransmitter release.

As depicted in Figure 15-23, cGMP phosphodiesterase is the effector protein for $G_{\alpha t}$, both of which are localized to the disk membrane of the rod cell. The free $G_{\alpha t}$ •GTP complex that is generated after light absorption by rhodopsin binds to the two inhibitory γ subunits of cGMP phosphodiesterase, releasing the active catalytic α and β subunits, which then convert cGMP to GMP. This is a clear example of how signal-induced removal of an inhibitor can quickly activate an enzyme, a common mechanism in signaling pathways. In turn, the lowered concentration of cGMP leads to closing of the cGMP-gated ion channel in the rod cell plasma membrane, thereby reducing neurotransmitter release.

Direct support for the role of cGMP in rod-cell activity has been obtained in patch-clamping studies using isolated patches of rod outer-segment plasma membrane, which contains abundant cGMP-gated cation channels. When cGMP is added to the cytosolic surface of these patches, there is a rapid increase in the number of open ion channels; cGMP binds directly to a site on the channel protein to keep them open. Like the K^+ channels discussed in Chapter 11, the cGMP-gated channel protein contains four subunits (see Figure 11-20). In this case, each of the subunits is able to bind a cGMP molecule. Three or four cGMP molecules must bind per channel in order to open it; this allosteric interaction makes channel opening very sensitive to small changes in cGMP levels.

Conversion of active $G_{\alpha t}$ •GTP back to inactive $G_{\alpha t}$ •GDP is accelerated by a specific GTPase-activating protein (GAP).

FIGURE 15-23 Light-activated rhodopsin pathway and the closing of cation channels in rod cells. In dark-adapted rod cells, a high level of cGMP keeps nucleotide-gated nonselective cation channels open, leading to depolarization of the plasma membrane and neurotransmitter release. Light absorption generates activated rhodopsin, R^* (step 1), which binds inactive GDP-bound $G_{\alpha t}$ protein and mediates replacement of GDP with GTP (step 2). The free $G_{\alpha t}$ -GTP generated then activates cGMP phosphodiesterase (PDE) by binding to its inhibitory γ subunits (step 3) and dissociating them from the catalytic α and β subunits (step 4). Relieved of their inhibition, the α

and β subunits of PDE hydrolyze cGMP to GMP (step 5). The resulting decrease in cytosolic cGMP leads to dissociation of cGMP from the nucleotide-gated channels in the plasma membrane and closing of the channels (step 6). The membrane then becomes transiently hyperpolarized, and neurotransmitter release is reduced. The complex of $G_{\alpha t}$ -GTP and the PDE γ subunits binds a GTPase activating complex termed RGS9-G β 5 (step 7); by hydrolyzing the bound GTP, this triggers the physiologically rapid inactivation of the phosphodiesterase. [Adapted from V. Arshavsky and E. Pugh, 1998, *Neuron* 20:11, and V. Arshavsky, 2002, *Trends Neurosci.* 25:124.]

In mammals, $G_{\alpha t}$ normally remains in the active GTP-bound state for only a fraction of a second. Thus cGMP phosphodiesterase rapidly becomes inactivated, and the cGMP level gradually rises to its original level when the light stimulus is removed. This allows rapid responses of the eye toward moving or changing objects.

Signal Amplification Makes the Rhodopsin Signal Transduction Pathway Exquisitely Sensitive

Remarkably, a single photon absorbed by a resting rod cell produces a measurable response, a more inside-negative change in the membrane potential of about 1 mV, which in amphibians lasts a second or two. Humans are able to detect a flash of as few as five photons. The light-detecting system is so sensitive because the signal is greatly amplified during the

signal transduction pathway. Each activated opsin in the disk membrane of the rod cell can activate 500 $G_{\alpha t}$ molecules, each of which in turn activates a cGMP phosphodiesterase. Each molecule of phosphodiesterase hydrolyzes hundreds of cGMP molecules during the fraction of a second it remains active. Thus absorbance of a single photon—yielding a single activated opsin molecule—can trigger closing of thousands of ion channels in the plasma membrane and a measurable change in the membrane potential of the cell.

Rapid Termination of the Rhodopsin Signal Transduction Pathway Is Essential for Acute Vision

As in all G protein-coupled signaling pathways, timely termination of the rhodopsin signaling pathway requires that all the activated intermediates be inactivated rapidly, restoring

the system to its basal state, ready for signaling again. Thus the three protein intermediates, activated rhodopsin (R^*), $G_{\alpha t}\cdot\text{GTP}$, and activated cGMP phosphodiesterase (PDE), must all be inactivated, and the concentration of cytoplasmic messenger cGMP must be restored to its dark level by guanylyl cyclase. During a single photon response of a mammalian rod cell, the entire process of rhodopsin activation and inactivation is completed within ~ 50 milliseconds, enabling the eye to detect rapid movements or other changes in objects in our surroundings. Several mechanisms act together to make possible this very rapid response.

GAP Proteins That Inactivate $G_{\alpha t}\cdot\text{GTP}$ The complex of the inhibitory γ phosphodiesterase subunit and $G_{\alpha t}\cdot\text{GTP}$ recruits a complex of two proteins, RGS9 and G $\beta 5$, that together act as a GAP protein and hydrolyze the bound GTP to GDP. This releases the inhibitory γ subunit and terminates phosphodiesterase activation. Experiments with mice that have the RGS9 gene knocked out showed that this protein is essential for normal inactivation of the cascade in vivo. In single mouse rod cells, the time for recovery from a single flash increased from the normal 0.2 s to about 9 s in the mutant, a 45-fold increase, attesting to the importance of this GAP protein.

Ca^{2+} -Sensing Proteins That Activate Guanylate Cyclase Light-triggered closing of the cGMP-gated Na^+ and Ca^{2+} channel will cause a drop in the cytosolic Ca^{2+} concentration

since Ca^{2+} is continuously pumped out of the cell independently of the state of these channels. The fall in intracellular Ca^{2+} is sensed by Ca^{2+} -binding proteins called guanylate-cyclase-activating proteins, or GCAPs. This results in a rapid stimulation of cGMP synthesis by guanylate cyclase, causing the ion channels to reopen.

Rhodopsin Phosphorylation and Binding of Arrestin A major process that down-modulates and terminates the visual response involves phosphorylation of rhodopsin in its active conformation (R^*) but not in its inactive, or dark form (R) by *rhodopsin kinase* (Figure 15-24), a member of a class of GPCR kinases. Each opsin molecule has three principal serine phosphorylation sites on its cytosol-facing C-terminal C4 segment; the more sites that are phosphorylated, the less able R^* is to activate $G_{\alpha t}$ and so induce closing of cGMP-gated cation channels. The protein *arrestin* binds to three phosphorylated serine residues on the C-terminal opsin segment. Bound arrestin completely prevents interaction of $G_{\alpha t}$ with phosphorylated R^* , totally blocking formation of the active $G_{\alpha t}\cdot\text{GTP}$ complex and stopping additional activation of cGMP phosphodiesterase. During a single photon response of a mammalian rod cell, the entire process of multiple rhodopsin phosphorylation and arrestin binding is completed within ~ 50 milliseconds. The phosphates linked to rhodopsin are being continuously removed by phosphodiesterase enzymes, causing dissociation of arrestin and rapid restoration of rhodopsin to its original, native state.

FIGURE 15-24 Inhibition of rhodopsin signaling by rhodopsin kinase. Light-activated rhodopsin (R^*), but not dark-adapted rhodopsin, is a substrate for rhodopsin kinase. The extent of rhodopsin phosphorylation is proportional to the amount of time each rhodopsin molecule spends in the light-activated form and reduces the ability of

R^* to activate transducin. Arrestin binds to the completely phosphorylated opsin, forming a complex that cannot activate transducin at all. [See A. Mendez et al., 2000, *Neuron* 28:153, and V. Arshavsky, 2002, *Trends Neurosci.* 25:124.]

Rod Cells Adapt to Varying Levels of Ambient Light by Intracellular Trafficking of Arrestin and Transducin

Cone cells are insensitive to low levels of illumination, and the activity of rod cells is inhibited at high light levels. Thus when we move from bright daylight into a dimly lighted room, we are initially blinded. Slowly, however, the rod cells become sensitive to the dim light, and we gradually are able to see and distinguish objects. During this interval, the rod cell has “turned up” its sensitivity to flashes of light, or contrast. Through this process of *visual adaptation*, a rod cell can perceive contrast over a 100,000-fold range of ambient

light levels, from very dim to bright sunlight. This wide range of sensitivity is possible because differences in light levels in the visual field, rather than the absolute amount of absorbed light, are ultimately sensed by the brain and used to form visual images. A mechanism for light-dependent regulation of the rhodopsin-signaling pathway that involves subcellular trafficking of two key signal transduction proteins (Figure 15-25) is responsible for this extraordinarily wide sensitivity range.

In dark-adapted rod cells, ~80 to 90 percent of the $G_{\alpha t}$ and $G_{\beta\gamma}$ transducin subunits are in the outer segments, while less than 10 percent of arrestin is localized there (Figure 15-25). This allows maximal activation of the downstream effector cGMP phosphodiesterase and thus maximal sensitivity to small changes in light. But exposure for 10 minutes to moderate daytime intensities of light causes a complete redistribution of these proteins: over 80 percent of the $G_{\alpha t}$ and $G_{\beta\gamma}$ subunits move out of the outer segment into other parts of the cell while over 80 percent of the inhibitor arrestin moves into the outer segment. The mechanism by which these proteins move is not yet known but probably involves microtubule-attached motors that move attached proteins and particles outward and inward (see Chapter 18). The reduction in $G_{\alpha t}$ and $G_{\beta\gamma}$ in the outer segment means that $G_{\alpha t}$ proteins are physically unable to bind activated rhodopsin and so activate cGMP phosphodiesterase. At the same time, the increase in arrestin in the outer segment means that any activated rhodopsin will become inactivated more rapidly. Together, the drop in transducin and the increase in arrestin greatly reduce the ability of small increases in light levels to activate the downstream effector cGMP phosphodiesterase; thus only large changes in light levels will be sensed by the rod cells. These protein movements are reversed when the ambient light level is lowered.

FIGURE 15-25 Schematic illustration of transducin and arrestin distribution in dark-adapted and light-adapted rod cells. (a) In the dark, most transducin is localized to the outer segment, while most arrestin is found in other parts of the cell; in this condition vision is most sensitive to very low light levels. (b) In bright light, little transducin is found in the outer segment and abundant arrestin is found there; in this condition vision is relatively insensitive to small changes in light. Coordinated movement of these proteins contributes to our ability to perceive images over a 100,000-fold range of ambient light levels. [After P. Calvert et al., 2006, *Trends Cell Biol.* 16:560.]

KEY CONCEPTS of Section 15.4

G Protein–Coupled Receptors That Regulate Ion Channels

- The cardiac muscarinic acetylcholine receptor is a GPCR whose effector protein is a K^+ channel. Receptor activation releases the $G_{\beta\gamma}$ subunit, which binds to and opens K^+ channels (see Figure 15-20). The resulting hyperpolarization of the cell membrane slows the rate of heart muscle contraction.
- Rhodopsin, the photosensitive GPCR in rod cells, comprises the protein opsin linked to 11-*cis*-retinal. Light-induced isomerization of the 11-*cis*-retinal moiety produces activated opsin, which then activates the coupled trimeric G protein transducin (G_t) by catalyzing exchange of free GTP for bound GDP on the $G_{\alpha t}$ subunit (see Figures 15-22 and 15-23).
- The effector protein in the rhodopsin pathway is cGMP phosphodiesterase, which is activated by the $G_{\alpha t}$ -GTP-mediated release of inhibitory subunits. Reduction in the cGMP level by this enzyme leads to closing of cGMP-gated

$\text{Na}^+/\text{Ca}^{2+}$ channels, hyperpolarization of the membrane, and decreased release of neurotransmitter (see Figure 15-23).

- Several mechanisms act to terminate visual signaling: GAP proteins inactivate $\text{G}_{\text{at}}\cdot\text{GTP}$, Ca^{2+} -sensing proteins activate guanylate cyclase, and rhodopsin phosphorylation and binding of arrestin inhibits activation of transducin.
- Adaptation to a wide range of ambient light levels is mediated by movements of transducin and arrestin into and out of the rod-cell outer segment, which together modulate the ability of small increases in light levels to activate the downstream effector cGMP phosphodiesterase and thus the sensitivity of the rod cell in different ambient levels of light.

15.5 G Protein–Coupled Receptors That Activate or Inhibit Adenylyl Cyclase

GPCR pathways that utilize adenylyl cyclase as an effector protein and cAMP as the second messenger are found in most mammalian cells, where they regulate cellular functions as diverse as metabolism of fats and sugars, synthesis and secretion of hormones, and muscle contraction. These pathways follow the general GPCR mechanism outlined in Figure 15-17: ligand binding to the receptor activates a coupled trimeric G protein that activates an effector protein—in this case, adenylyl cyclase, which synthesizes the diffusible second messenger cAMP from ATP (Figure 15-26). cAMP, in turn, activates a cAMP-dependent protein kinase that phosphorylates specific target proteins.

To explore this GPCR/cAMP pathway, we focus on the first such pathway discovered: the hormone-stimulated generation of glucose-1-phosphate from glycogen, a storage polymer of glucose. The breakdown of glycogen (*glycogenolysis*) occurs in muscle and liver cells in response to hormones such as epinephrine and glucagon and is a principal way that glucose is made available to cells in need of energy. This example shows how activation of a GPCR can stimulate the activity of a host of intracellular enzymes, all involved in a physiologically important task: glycogen metabolism.

Adenylyl Cyclase Is Stimulated and Inhibited by Different Receptor-Ligand Complexes

Under conditions where demand for glucose is high because of low blood sugar, *glucagon* is released by the alpha cells in the pancreatic islets; in case of sudden stress, epinephrine is released by the adrenal glands. Both glucagon and epinephrine signal liver and muscle cells to depolymerize glycogen, releasing individual glucose molecules. In the liver, glucagon and epinephrine bind to different G protein–coupled receptors, but both receptors interact with and activate the same stimulatory G_s protein that activates adenylyl cyclase. Hence both hormones induce the same metabolic responses. Activation of adenylyl cyclase, and thus the cAMP level, is proportional to

FIGURE 15-26 Synthesis and hydrolysis of cAMP by adenylyl cyclase and cAMP phosphodiesterase. Similar reactions occur for production of cGMP from GTP and hydrolysis of cGMP.

the total concentration of $\text{G}_{\text{as}}\cdot\text{GTP}$ resulting from binding of both hormones to their respective receptors.

Positive (activation) and negative (inhibition) regulation of adenylyl cyclase activity occurs in many cell types, providing fine-tuned control of the cAMP level and so of the downstream cellular response (Figure 15-27). For example, in adipose cells the breakdown of triacylglycerols to fatty acids and glycerol (*lipolysis*) is stimulated by binding of epinephrine, glucagon, or adrenocorticotrophic hormone (ACTH) to separate receptors that activate adenylyl cyclase. Conversely, binding of two other hormones, prostaglandin E_1 (PGE_1) or adenosine, to their respective G protein–coupled receptors inhibits adenylyl cyclase. The prostaglandin and adenosine receptors activate an inhibitory G_i protein that contains the same β and γ subunits as the stimulatory G_s protein but a different α subunit (G_{oi}). After the active $\text{G}_{\text{oi}}\cdot\text{GTP}$ complex dissociates from $\text{G}_{\beta\gamma}$, it binds to but inhibits (rather than stimulates) adenylyl cyclase, resulting in lower cAMP levels.

FIGURE 15-27 Hormone-induced activation and inhibition of adenylyl cyclase in adipose cells. Ligand binding to $G_{\alpha s}$ -coupled receptors causes activation of adenylyl cyclase, whereas ligand binding to $G_{\alpha i}$ -coupled receptors causes inhibition of the enzyme. The $G_{\beta\gamma}$ subunit in both stimulatory and inhibitory G proteins is identical; the G_{α} subunits

and their corresponding receptors differ. Ligand-stimulated formation of active G_{α} -GTP complexes occurs by the same mechanism in both $G_{\alpha s}$ and $G_{\alpha i}$ proteins (see Figure 15-17). However, $G_{\alpha s}$ -GTP and $G_{\alpha i}$ -GTP interact differently with adenylyl cyclase, so that one stimulates and the other inhibits its catalytic activity. [See A. G. Gilman, 1984, *Cell* 36:577.]

Structural Studies Established How $G_{\alpha s}$ -GTP Binds to and Activates Adenylyl Cyclase

X-ray crystallographic analysis has pinpointed the regions in $G_{\alpha s}$ -GTP that interact with adenylyl cyclase. This enzyme is a multispanning transmembrane protein with two large cytosolic segments containing the catalytic domains that convert ATP to cAMP (Figure 15-28a). Because such transmembrane proteins are notoriously difficult to crystallize, scientists prepared two protein fragments encompassing the two catalytic domains of adenylyl cyclase that tightly associate with each other in a heterodimer. When these catalytic fragments are allowed to associate in the presence of $G_{\alpha s}$ -GTP and forskolin (a plant chemical that binds to and activates adenylyl cyclase), they are stabilized in their active conformations.

The resulting water-soluble complex (two adenylyl cyclase domain fragments/ $G_{\alpha s}$ -GTP/forskolin) had an enzymatic activity synthesizing cAMP similar to that of intact full-length adenylyl cyclase. In this complex, two regions of

$G_{\alpha s}$ -GTP—the switch II helix and the $\alpha 3$ - $\beta 5$ loop—contact the adenylyl cyclase fragments (Figure 15-28b). These contacts are thought to be responsible for the activation of the enzyme by $G_{\alpha s}$ -GTP. Recall that switch II is one of the segments of a G_{α} subunit whose conformation is different in the GTP-bound and GDP-bound states (see Figure 15-7). The GTP-induced conformation of $G_{\alpha s}$ that favors its dissociation from $G_{\beta\gamma}$ is precisely the conformation essential for binding of $G_{\alpha s}$ to adenylyl cyclase.

FIGURE 15-28 Structure of mammalian adenylyl cyclase and its interaction with $G_{\alpha s}$ -GTP. (a) Schematic diagram of mammalian adenylyl cyclase. The membrane-bound enzyme contains two similar catalytic domains, which convert ATP to cAMP, on the cytosolic face of the membrane, and two integral membrane domains, each of which is thought to contain six transmembrane α helices. (b) Model of the three-dimensional structure of $G_{\alpha s}$ -GTP complexed with two fragments encompassing one catalytic domain of adenylyl cyclase determined by x-ray crystallography. The $\alpha 3$ - $\beta 5$ loop (gray) and the helix in the switch II region (blue) of $G_{\alpha s}$ -GTP interact simultaneously with a specific region of adenylyl cyclase. The darker-colored part of $G_{\alpha s}$ is the GTP-binding domain, which is similar in structure to Ras (see Figure 15-7); the lighter part is a helical domain. The two adenylyl cyclase fragments are shown in orange and yellow. Forskolin (green) locks the cyclase fragments in their active conformations. [Part (a), see W.-J. Tang and A. G. Gilman, 1992, *Cell* 70:869; part (b) adapted from J. J. G. Tesmer et al., 1997, *Science* 278:1907.]

cAMP Activates Protein Kinase A by Releasing Inhibitory Subunits

The second messenger cAMP, synthesized by adenylyl cyclase, transduces a wide variety of physiological signals in different cell types in multicellular animals. Virtually all of the diverse effects of cAMP are mediated through activation of **protein kinase A (PKA)**, also called *cAMP-dependent protein kinase*, which phosphorylates different intracellular target proteins expressed in different cell types. Inactive PKA is a tetramer consisting of two regulatory (R) subunits and two catalytic (C) subunits (Figure 15-29a). Each R subunit binds to the active site in a catalytic domain and inhibits the activity of the catalytic subunits. Inactive PKA is turned on by

binding of cAMP. Each R subunit has two distinct cAMP-binding sites, called CNB-A and CNB-B (Figure 15-29b). Binding of cAMP to both sites on an R subunit causes a conformational change in the R subunit that leads to release of the associated C subunit, unmasking its catalytic site and activating its kinase activity (Figure 15-29c).

Binding of cAMP by an R subunit of protein kinase A occurs in a cooperative fashion; that is, binding of the first cAMP molecule to CNB-B lowers the K_d for binding of the second cAMP to CNB-A. Thus small changes in the level of cytosolic cAMP can cause proportionately large changes in the number of dissociated C subunits and, hence, in cellular kinase activity. Rapid activation of enzymes by hormone-triggered dissociation of an inhibitor is a common feature of many signaling pathways.

Glycogen Metabolism Is Regulated by Hormone-Induced Activation of Protein Kinase A

Glycogen, a large glucose polymer, is the major storage form of glucose in animals. Like all biopolymers, glycogen is synthesized by one set of enzymes and degraded by another (Figure 15-30). Degradation of glycogen, or glycogenolysis, involves the stepwise removal of glucose residues from one end of the polymer by a phosphorolysis reaction, catalyzed by *glycogen phosphorylase*, yielding glucose 1-phosphate.

In both muscle and liver cells, glucose-1-phosphate produced from glycogen is converted to glucose-6-phosphate. In muscle cells, this metabolite enters the glycolytic pathway and is metabolized to generate ATP for use in powering muscle contraction (see Chapter 12). Unlike muscle cells, liver cells contain a phosphatase that hydrolyzes glucose-6-phosphate to glucose, which is exported from these cells mainly by a glucose transporter (GLUT2) in the plasma membrane (see Chapter 11). Thus glycogen stores in the liver are primarily broken down to glucose, which is immediately released into the blood and transported to other tissues, particularly the muscles and brain, to nourish them.

FIGURE 15-29 Structure of protein kinase A (PKA) and its activation by cAMP.

(a) Protein kinase A (PKA) consists of two regulatory (R) subunits (green) and two catalytic (C) subunits. When cAMP (red triangle) binds to the regulatory subunit, the catalytic subunit is released, thus activating PKA. (b) The two regulatory subunits form a dimer, joined by a dimerization/docking domain and a flexible linker to which A-kinase-activating protein (AKAP; see Figure 15-33) can bind. Each R subunit has two cAMP-binding domains, CNB-A and CNB-B, and a binding site for a catalytic subunit (arrow). (c) Binding of cAMP to the CNB-A domain causes a subtle conformational change that displaces the catalytic subunit from R, leading to its activation. Without bound cAMP, one loop of the CNB-A domain (purple) is in a conformation that can bind the catalytic (C) subunit. A glutamate (E200) and arginine (R209) residue participate in binding of cAMP (red), which causes a conformational change (green) in the loop that prevents binding of the loop to the C subunit. [Part (b) after S. S. Taylor et al., 2005, *Biochim. Biophys. Acta* 1754:25; part (c) after C. Kim, N. H. Xuong, and S. S. Taylor, 2005, *Science* 307:690.]

FIGURE 15-30 Synthesis and degradation of glycogen. Incorporation of glucose from UDP-glucose into glycogen is catalyzed by glycogen synthase. Removal of glucose units from glycogen is

catalyzed by glycogen phosphorylase. Because two different enzymes catalyze the formation and degradation of glycogen, the two reactions can be independently regulated.

The epinephrine-stimulated activation of adenylyl cyclase, resulting increase in cAMP, and subsequent activation of protein kinase A (PKA) enhances the conversion of glycogen to glucose-1-phosphate in two ways: by *inhibiting* glycogen synthesis and by *stimulating* glycogen degradation (Figure 15-31a). PKA phosphorylates and in so doing inactivates glycogen synthase (GS), the enzyme that synthesizes glycogen. PKA promotes glycogen degradation indirectly by phosphorylating and thus activating an intermediate kinase, glycogen phosphorylase kinase (GPK), that in turn phosphorylates and activates glycogen phosphorylase (GP), the enzyme that degrades glycogen. These kinases are counteracted by a phosphatase called phosphoprotein phosphatase (PP). At high cAMP levels, PKA phosphorylates an inhibitor of phosphoprotein phosphatase (IP), which keeps this phosphatase in its inactive state (see Figure 15-31a, *right*).

The entire process is reversed when epinephrine is removed and the level of cAMP drops, inactivating protein kinase A (PKA). When PKA is inactive, it can no longer phosphorylate the inhibitor of phosphoprotein phosphatase (IP), so this phosphatase becomes active (Figure 15-31b). Phosphoprotein phosphatase (PP) removes the phosphate residues previously added by PKA to glycogen synthase (GS), glycogen phosphorylase kinase (GPK), and glycogen phos-

phorylase (GP). As a consequence, the synthesis of glycogen by glycogen synthase is enhanced and the degradation of glycogen by glycogen phosphorylase is inhibited.

Epinephrine-induced glycogenolysis thus exhibits dual regulation: activation of the enzymes catalyzing glycogen degradation and inhibition of enzymes promoting glycogen synthesis. Such dual regulation provides an efficient mechanism for regulating a particular cellular response and is a common phenomenon in cell biology.

cAMP-Mediated Activation of Protein Kinase A Produces Diverse Responses in Different Cell Types

In adipose cells, epinephrine-induced activation of protein kinase A (PKA) promotes phosphorylation and activation of the lipase that hydrolyzes stored triglycerides to yield free fatty acids and glycerol. These fatty acids are released into the blood and taken up as an energy source by cells in other tissues such as the kidney, heart, and muscles (see Chapter 12). Therefore, activation of PKA by epinephrine in two different cell types, liver and adipose, has different effects. Indeed, cAMP and PKA mediate a large array of hormone-induced cellular responses in numerous tissues (Table 15-2).

FIGURE 15-31 Regulation of glycogen metabolism by cAMP and PKA. Active enzymes are highlighted in darker shades; inactive forms, in lighter shades. (a) An increase in cytosolic cAMP activates protein kinase A (PKA), which inhibits glycogen synthesis directly and promotes glycogen degradation via a protein kinase cascade. At high cAMP, PKA also phosphorylates an inhibitor of phosphoprotein

phosphatase (PP). Binding of the phosphorylated inhibitor to PP prevents this phosphatase from dephosphorylating the activated enzymes in the kinase cascade or the inactive glycogen synthase. (b) A decrease in cAMP inactivates PKA, leading to release of the active form of PP. The action of this enzyme promotes glycogen synthesis and inhibits glycogen degradation.

Although protein kinase A acts on different substrates in different types of cells, it always phosphorylates a serine or threonine residue that occurs within the same sequence motif: X-Arg-(Arg/Lys)-X-(Ser/Thr)-Φ, where X denotes any amino acid and Φ denotes a hydrophobic amino acid. Other serine/threonine kinases phosphorylate target residues within other sequence motifs.

Signal Amplification Occurs in the cAMP-Protein Kinase A Pathway

We've seen that receptors such as the β-adrenergic receptor are low-abundance proteins, typically present in only a few thousand copies per cell. Yet the cellular responses induced by a hormone such as epinephrine can require production of large numbers of cAMP and activated enzyme molecules per cell. As an example, following activation of G_{as} -coupled receptors, the intracellular concentration of cAMP will rise to about 10^{-6} M; in a typical cell that is a cube $\sim 15 \mu\text{m}$ on a side, this comes to ~ 2 million molecules of cAMP produced per cell. Thus substantial amplification of the signal is necessary in order for the hormone to induce a significant cellular response. We have already seen how signal amplification occurs following photon absorbance in rod cells. In the case of G protein-coupled hormone receptors, signal amplification is possible in part because both receptors and G proteins can diffuse rapidly in the plasma membrane. A single epinephrine-GPCR complex causes con-

version of up to 100 inactive G_{as} molecules to the active form before epinephrine dissociates from the receptor. Each active G_{as} -GTP, in turn, activates a single adenylyl cyclase molecule, which then catalyzes synthesis of many cAMP molecules during the time G_{as} -GTP is bound to it.

The amplification that occurs in such a signal transduction cascade depends on the number of steps in it and the relative concentrations of the various components. In the epinephrine-induced cascade shown in Figure 15-9, for example, blood levels of epinephrine as low as 10^{-10} M can stimulate liver glycogenolysis and release of glucose. An epinephrine stimulus of this magnitude generates an intracellular cAMP concentration of 10^{-6} M, an amplification of 10^4 -fold. Because three more catalytic steps precede the release of glucose, another 10^4 amplification can occur, resulting in a 10^8 amplification of the epinephrine signal. In striated muscle, the amplification is less dramatic because the concentrations of the three successive enzymes in the glycogenolytic cascade—protein kinase A, glycogen phosphorylase kinase, and glycogen phosphorylase—are in a 1:10:240 ratio (a potential 240-fold maximal amplification).

CREB Links cAMP and Protein Kinase A to Activation of Gene Transcription

Activation of protein kinase A also stimulates the expression of many genes, leading to long-term effects on the cells that often enhance the short-term effects of activated protein kinase A.

TABLE 15-2 Cellular Responses to Hormone-Induced Rise in cAMP in Various Tissues*

Tissue	Hormone Inducing Rise in cAMP	Cellular Response
Adipose	Epinephrine; ACTH; glucagon	Increase in hydrolysis of triglyceride; decrease in amino acid uptake
Liver	Epinephrine; norepinephrine; glucagon	Increase in conversion of glycogen to glucose; inhibition of glycogen synthesis; increase in amino acid uptake; increase in gluconeogenesis (synthesis of glucose from amino acids)
Ovarian follicle	FSH; LH	Increase in synthesis of estrogen, progesterone
Adrenal cortex	ACTH	Increase in synthesis of aldosterone, cortisol
Cardiac muscle	Epinephrine	Increase in contraction rate
Thyroid gland	TSH	Secretion of thyroxine
Bone	Parathyroid hormone	Increase in resorption of calcium from bone
Skeletal muscle	Epinephrine	Conversion of glycogen to glucose-1-phosphate
Intestine	Epinephrine	Fluid secretion
Kidney	Vasopressin	Resorption of water
Blood platelets	Prostaglandin I	Inhibition of aggregation and secretion

*Nearly all the effects of cAMP are mediated through protein kinase A (PKA), which is activated by binding of cAMP.
SOURCE: E. W. Sutherland, 1972, *Science* 177:401.

For instance, in liver cells, protein kinase A induces expression of several enzymes involved in gluconeogenesis—the conversion of three-carbon compounds such as pyruvate (see Figure 12-3) to glucose—thus increasing the level of glucose in the blood.

All genes regulated by protein kinase A contain a cis-acting DNA sequence, the *cAMP-response element* (CRE), that binds the phosphorylated form of a transcription factor called *CRE-binding* (CREB) *protein*, which is found only in the nucleus. Following the elevation of cAMP levels and the release of the active protein kinase A catalytic subunit, some of the catalytic subunits then translocate to the nucleus. There they phosphorylate serine-133 on the CREB protein. Phosphorylated CREB protein binds to CRE-containing target genes and also binds to a *co-activator* termed *CBP/300*. CBP/300 links CREB to RNA polymerase 2 and other gene regulatory proteins, thereby stimulating gene transcription (Figure 15-32).

Thus protein kinase A phosphorylates multiple types of proteins: some have relatively short-term effects on cellular metabolism, lasting seconds to minutes; other substrates such as CREB, by activating expression of specific genes, affect cellular metabolism over hours and days.

Anchoring Proteins Localize Effects of cAMP to Specific Regions of the Cell

In many cell types, a rise in the cAMP level may produce a response that is required in one part of the cell but is unneeded, perhaps deleterious, in another. A family of anchoring proteins

localizes isoforms of protein kinase A (PKA) to specific subcellular locations, thereby restricting cAMP-dependent responses to these locations. These proteins, referred to as *A kinase-associated proteins* (AKAPs), have a two-domain structure with one domain conferring a specific subcellular location and another that binds to the regulatory (R) subunit of protein kinase A (see Figure 15-29b).

One such anchoring protein (AKAP15) is tethered to the cytosolic face of the plasma membrane near a particular type of gated Ca^{2+} channel in certain heart muscle cells. In the heart, activation of β -adrenergic receptors by epinephrine (as part of the fight-or-flight response) leads to PKA-catalyzed phosphorylation of these Ca^{2+} channels, causing them to open; the resulting influx of Ca^{2+} increases the rate of heart muscle contraction. The binding of AKAP15 to protein kinase A localizes the kinase next to these channels, thereby reducing the time that otherwise would be required for diffusion of PKA catalytic subunits from their sites of generation to their Ca^{2+} -channel substrates.

A different AKAP in heart muscle anchors both protein kinase A and cAMP phosphodiesterase (PDE)—the enzyme that hydrolyzes cAMP to AMP (see Figure 15-26)—to the outer nuclear membrane. Because of the close proximity of PDE to protein kinase A, negative feedback provides tight local control of the cAMP concentration and hence local PKA activity (Figure 15-33). As cAMP levels rise in response to hormone stimulation, PKA is activated. Activated PKA phosphorylates PDE, which in turn becomes more active and

FIGURE 15-32 Activation of CREB transcription factor following ligand binding to G_s protein-coupled receptors. Receptor stimulation (1) leads to activation of protein kinase A (PKA) (2). Catalytic subunits of PKA translocate to the nucleus (3) and there phosphorylate and activate the CREB transcription factor (4). Phosphorylated CREB associates with the co-activator CBP/P300 (5) and other proteins to stimulate transcription of the various target genes controlled by the CRE regulatory element. [See K. A. Lee and N. Masson, 1993, *Biochim. Biophys. Acta* 1174:221, and D. Parker et al., 1996, *Mol. Cell Biol.* 16(2):694.]

hydrolyzes cAMP, thus returning PKA to its inactive state. The localization of protein kinase A near the nuclear membrane also facilitates entry of its catalytic subunits into the nucleus, where they phosphorylate and activate the CREB transcription factor (see Figure 15-32).

Multiple Mechanisms Down-Regulate Signaling from the GPCR/cAMP/PKA Pathway

For cells to respond effectively to changes in their environment, they must not only activate a signaling pathway but also down-modulate or terminate the response once it is no longer needed; otherwise signal transduction pathways would remain “on” too long or at too high a level and the cell would become overstimulated. Abnormal regulation of signaling pathways is very common in cancer cells, where mutant proteins that stimulate cell proliferation or prevent programmed cell death remain active even when the signals that normally activate them are absent.

FIGURE 15-33 Localization of protein kinase A (PKA) to the nuclear membrane in heart muscle by an A-kinase-associated protein (AKAP). This member of the AKAP family, designated mAKAP, anchors both cAMP phosphodiesterase (PDE) and the regulatory subunit (R, see Figure 15-29b) of PKA to the nuclear membrane, maintaining them in a negative feedback loop that provides close local control of the cAMP level and PKA activity. Step 1: The basal level of PDE activity in the absence of hormone (resting state) keeps cAMP levels below those necessary for PKA activation. Steps 2 and 3: Activation of β -adrenergic receptors causes an increase in cAMP level

in excess of that which can be degraded by PDE. The resulting binding of cAMP to the regulatory (R) subunits of PKA releases the active catalytic (C) subunits into the cytosol. Some C subunits enter into the nucleus, where they phosphorylate and thus activate certain transcription factors (see Figure 15-32). Other C subunits phosphorylate PDE, stimulating its catalytic activity. Active PDE hydrolyzes cAMP, thereby driving cAMP levels back to basal levels and causing re-formation of the inactive PKA-R complex. Step 4: Subsequent dephosphorylation of PDE returns the complex to the resting state. [Adapted from K. L. Dodge et al., 2001, *EMBO J.* 20:1921.]

Earlier we saw the multiple mechanisms that rapidly terminate the rhodopsin signal transduction pathway, including GAP proteins that stimulate the hydrolysis of GTP bound to G_{α} , Ca^{2+} -sensing proteins that activate guanylate cyclase, and phosphorylation of active rhodopsin by rhodopsin kinase followed by binding of arrestin (see Figure 15-24). In fact, most G protein-coupled receptors are modulated by multiple mechanisms that down-regulate their activity, as is exemplified by β -adrenergic receptors and others coupled to $G_{\alpha s}$ that activate adenylyl cyclase.

- First, the affinity of the receptor for its ligand decreases when the GDP bound to $G_{\alpha s}$ is replaced with GTP. This increase in the K_d of the receptor-hormone complex enhances dissociation of the ligand from the receptor and thereby limits the number of $G_{\alpha s}$ proteins that are activated.
- Second, the intrinsic GTPase activity of $G_{\alpha s}$ converts the bound GTP to GDP, resulting in inactivation of $G_{\alpha s}$ and decreased activation of its downstream target adenylyl cyclase. Importantly, the rate of hydrolysis of GTP bound to $G_{\alpha s}$ is enhanced when $G_{\alpha s}$ binds to adenylyl cyclase, lessening the duration of cAMP production; thus adenylyl cyclase functions as a GAP for $G_{\alpha s}$. More generally, binding of most if not all G_{α} -GTP complexes to their respective effector proteins accelerates the rate of GTP hydrolysis.
- Finally, cAMP phosphodiesterase acts to hydrolyze cAMP to 5'-AMP, terminating the cellular response. Thus the continuous presence of hormone at a high enough concentration is required for continuous activation of adenylyl cyclase and maintenance of an elevated cAMP level. Once the hormone concentration falls sufficiently, the cellular response quickly terminates.

Most GPCRs are also down-regulated by *feedback repression*, a term describing the situation in which the end product of a signaling pathway blocks an early step in the pathway. For instance, when a $G_{\alpha s}$ protein-coupled receptor is exposed to hormonal stimulation for several hours, several serine and threonine residues in the cytosolic domain of the receptor become phosphorylated by protein kinase A (PKA), the end product of the $G_{\alpha s}$ signaling pathway. The phosphorylated receptor can bind its ligand but cannot efficiently activate $G_{\alpha s}$; thus ligand binding to the phosphorylated receptor leads to reduced activation of adenylyl cyclase compared with a nonphosphorylated receptor. Because the activity of PKA is enhanced by the high cAMP level induced by any hormone that activates $G_{\alpha s}$, prolonged exposure to one such hormone, say, epinephrine, desensitizes not only β -adrenergic receptors but also other $G_{\alpha s}$ protein-coupled receptors that bind different ligands (e.g., glucagon receptor in liver). This cross-regulation is called *heterologous desensitization*.

Similar to phosphorylation of activated rhodopsin by rhodopsin kinase, particular residues in the cytosolic domain of the β -adrenergic receptor, not those phosphorylated by PKA, can be phosphorylated by the related enzyme *β -adrenergic receptor kinase* (BARK), but *only* when epinephrine or an agonist is bound to the receptor and thus the receptor is in its active

conformation. This process is called *homologous desensitization*, because only those receptors that are in their active conformations are subject to deactivation by phosphorylation.

We noted that binding of arrestin to extensively phosphorylated opsin completely inhibits activation of coupled G proteins by activated opsin (see Figure 15-24). In fact, a related protein termed *β -arrestin* plays a similar role in desensitizing other G protein-coupled receptors, including β -adrenergic receptors. An additional function of β -arrestin in regulating cell-surface receptors initially was suggested by the observation that disappearance of β -adrenergic receptors from the cell surface in response to ligand binding is stimulated by overexpression of BARK and β -arrestin. Subsequent studies revealed that β -arrestin binds not only to phosphorylated receptors but also to clathrin and an associated protein termed AP2, two key components of the coated vesicles that are involved in one type of endocytosis from the plasma membrane (Figure 15-34). These interactions promote the formation of coated pits and endocytosis of the associated receptors, thereby decreasing the number of receptors exposed on the cell surface. Eventually some of the internalized receptors are degraded intracellularly, and some are dephosphorylated in endosomes. Following dissociation of β -arrestin, the resensitized (dephosphorylated) receptors recycle to the cell surface, similar to recycling of the LDL receptor (see Chapter 14).

FIGURE 15-34 Role of β -arrestin in GPCR desensitization and signal transduction. β -Arrestin binds to phosphorylated serine and threonine residues in the C-terminal segment of G protein-coupled receptors (GPCRs). Clathrin and AP2, two other proteins bound by β -arrestin, promote endocytosis of the receptor. β -Arrestin also functions in transducing signals from activated receptors by binding to and activating several cytosolic protein kinases. c-Src activates the MAP kinase pathway, leading to phosphorylation of key transcription factors (see Chapter 16). Interaction of β -arrestin with three other proteins, including JNK-3 (a Jun N-terminal kinase), results in phosphorylation and activation of another transcription factor, c-Jun. [Adapted from W. Miller and R. J. Lefkowitz, 2001, *Curr. Opin. Cell Biol.* 13:139, and K. Pierce et al., 2002, *Nature Rev. Mol. Cell Biol.* 3:639.]

In addition to its role in regulating receptor activity, β -arrestin functions as an adapter protein in transducing signals from G protein–coupled receptors to the nucleus (see Chapter 16). The GPCR–arrestin complex acts as a scaffold for binding and activating several cytosolic kinases (see Figure 15-34), which we discuss in detail in subsequent chapters. These include c-Src, a cytosolic protein tyrosine kinase that activates the MAP kinase pathway and other pathways leading to transcription of genes needed for cell division (see Chapter 19). A complex of three arrestin-bound proteins, including a Jun N-terminal kinase (JNK-3), initiates a kinase cascade that ultimately activates the c-Jun transcription factor, which promotes expression of certain growth-promoting enzymes and other proteins that help cells respond to stresses. Thus the BARK– β -arrestin pathway, originally just thought to suppress signaling by GPCRs, actually functions as a switch, turning off signaling by G proteins and turning on other signaling pathways. The multiple functions of β -arrestin illustrate the importance of adapter proteins in both regulating signaling and transducing signals from cell-surface receptors.

KEY CONCEPTS of Section 15.5

G Protein–Coupled Receptors That Activate or Inhibit Adenylyl Cyclase

- Ligand binding of G protein–coupled receptors that activate $G_{\alpha s}$ results in the activation of the membrane-bound enzyme adenylyl cyclase, which converts ATP to the second messenger cyclic AMP (cAMP; see Figure 15-26). Ligand binding of G protein–coupled receptors that activate $G_{\alpha i}$ results in the inhibition of adenylyl cyclase and lower levels of cAMP (see Figure 15-27).
- $G_{\alpha s}$ •GTP and $G_{\alpha i}$ •GTP bind to the heterodimeric active site domains in adenylyl cyclase to activate or inhibit the enzyme, respectively (see Figure 15-28).
- cAMP binds cooperatively to a regulatory subunit of protein kinase A (PKA), releasing the active kinase catalytic subunit (see Figure 15-29).
- PKA mediates the diverse effects of cAMP in most cells (see Table 15-2). The substrates for PKA, and thus the cellular response to hormone-induced activation of PKA, vary among cell types.
- In liver and muscle cells, activation of PKA induced by epinephrine and other hormones exerts a dual effect, inhibiting glycogen synthesis and stimulating glycogen breakdown via a kinase cascade (see Figure 15-31).
- The signal that activates the GPCR/adenylyl cyclase/cAMP/PKA signaling pathway is amplified tremendously by second messengers and kinase cascades (see Figure 15-9).
- Activation of PKA often leads to phosphorylation of nuclear CREB protein, which together with the CBP/300 co-activator stimulates transcription of genes, thus initiating a long-term change in the cell's protein composition (see Figure 15-32).

- Localization of PKA to specific regions of the cell by anchoring proteins restricts the effects of cAMP to particular subcellular locations (see Figure 15-33).
- Signaling from G_s -coupled receptors is down-regulated by multiple mechanisms: (1) the affinity of the receptor for its ligand decreases when the GDP bound to $G_{\alpha s}$ is replaced with GTP; (2) the intrinsic GTPase activity of $G_{\alpha s}$ that converts the bound GTP to GDP is enhanced when $G_{\alpha s}$ binds to adenylyl cyclase (this occurs when many G_{α} •GTP complexes bind to their respective effector proteins); and (3) cAMP phosphodiesterase acts to hydrolyze cAMP to 5'-AMP, terminating the cellular response.
- Most GPCRs are also down-regulated by *feedback repression*, in which the end product of a pathway (e.g., PKA) blocks an early step in the pathway. As with opsin, binding of β -arrestin to phosphorylated β -adrenergic receptors completely inhibits activation of coupled G proteins (see Figure 15-24).
- β -adrenergic receptors are deactivated by β -adrenergic kinase (BARK), which phosphorylates cytosolic residues of the receptor in its active conformation. BARK phosphorylation of ligand-bound β -adrenergic receptors also leads to the binding of β -arrestin and endocytosis of the receptors. The consequent reduction in the number of cell-surface receptors renders the cell less sensitive to additional hormone.
- The GPCR–arrestin complex functions as a scaffold that activates several cytosolic kinases, initiating cascades that lead to transcriptional activation of many genes controlling cell growth (see Figure 15-34).

15.6 G Protein–Coupled Receptors That Trigger Elevations in Cytosolic Ca^{2+}

Calcium ions play an essential role in regulating cellular responses to many signals, and many GPCRs and other types of receptors exert their effects on cells by influencing the cytosolic concentration of Ca^{2+} . As we saw in Chapter 11, the level of Ca^{2+} in the cytosol is maintained at a submicromolar level ($\sim 0.2 \mu\text{M}$) by the continuous action of ATP-powered Ca^{2+} pumps, which transport Ca^{2+} ions across the plasma membrane to the cell exterior or into the lumen of the endoplasmic reticulum and other vesicles. Much intracellular Ca^{2+} is also sequestered in mitochondria.

A small rise in cytosolic Ca^{2+} induces a variety of cellular responses, including hormone secretion by endocrine cells, secretion of digestive enzymes by pancreatic exocrine cells, and contraction of muscle (Table 15-3). For example, acetylcholine stimulation of GPCRs in secretory cells of the pancreas and parotid (salivary) gland induces a rise in cytosolic Ca^{2+} that triggers the fusion of secretory vesicles with the plasma membrane and release of their protein contents into the extracellular space. Thrombin, an enzyme in the blood-clotting cascade, binds to a GPCR on blood platelets and

TABLE 15-3 Cellular Responses to Hormone-Induced Rise in Cytosolic Ca^{2+} in Various Tissues*

Tissue	Hormone Inducing Rise in Ca^{2+}	Cellular Response
Pancreas (acinar cells)	Acetylcholine	Secretion of digestive enzymes, such as amylase and trypsinogen
Parotid (salivary) gland	Acetylcholine	Secretion of amylase
Vascular or stomach smooth muscle	Acetylcholine	Contraction
Liver	Vasopressin	Conversion of glycogen to glucose
Blood platelets	Thrombin	Aggregation, shape change, secretion of hormones
Mast cells	Antigen	Histamine secretion
Fibroblasts	Peptide growth factors	DNA synthesis, cell division (e.g., bombesin and PDGF)

*Hormone stimulation leads to production of inositol 1,4,5-trisphosphate (IP_3), a second messenger that promotes release of Ca^{2+} stored in the endoplasmic reticulum.

SOURCE: M. J. Berridge, 1987, *Ann. Rev. Biochem.* 56:159, and M. J. Berridge and R. F. Irvine, 1984, *Nature* 312:315.

triggers a rise in cytosolic Ca^{2+} that, in turn, causes a conformational change in the platelets that leads to their aggregation, an important step in blood clotting to prevent leakage of blood out of damaged blood vessels.

In this section, we first discuss an important signal transduction pathway that results in an elevation of cytosolic Ca^{2+} ions: the GPCR-stimulated activation of a **phospholipase C** (PLC). Phospholipases C (PLCs) are a family of enzymes that hydrolyzes a phosphoester bond in certain phospholipids, yielding two second messengers that function in elevating the cytosolic Ca^{2+} level and activating a family of kinases known as protein kinases C (PKCs); PKCs in turn affect many important cellular processes such as growth and differentiation. Some PLCs are activated by GPCRs, as we describe here; others, covered in the following chapter, are activated by other types of receptors. Phospholipase Cs also produce second messengers that are important for remodeling the actin cytoskeleton (see Chapter 17) and for binding of proteins important for endocytosis and vesicle fusions (see Chapter 14). Later in this section, we see how one PLC pathway leads to the synthesis of a gas, nitric oxide (NO), that in turn signals adjacent cells. In the final part of the section, we will see how second messengers such as Ca^{2+} are used to help cells integrate their responses to more than one extracellular signal.

Activated Phospholipase C Generates Two Key Second Messengers Derived from the Membrane Lipid Phosphatidylinositol

A number of important second messengers, used in several signal transduction pathways, are derived from the membrane lipid *phosphatidylinositol* (PI). The inositol group in this phospholipid, which always faces the cytosol, can be reversibly phosphorylated at one or more positions by the

combined actions of various kinases and phosphatases discussed in Chapter 16. One derivative of PI, the lipid phosphatidyl inositol 4,5-bisphosphate (PIP_2), is cleaved by activated phospholipase C into two important second messengers: **1,2-diacylglycerol** (DAG), a lipophilic molecule that remains associated with the membrane, and **inositol 1,4,5-trisphosphate** (IP_3), which can freely diffuse in the cytosol (Figure 15-35). We refer to downstream events involving these two second messengers collectively as the *IP_3 /DAG pathway*.

Phospholipase C is activated by G proteins containing either $G_{\alpha o}$ or $G_{\alpha q}$ subunits. In response to hormone activation of the GPCR, the $G_{\alpha o}$ or $G_{\alpha q}$ subunits bound to GTP separate from $G_{\beta\gamma}$ and bind to and activate phospholipase C in the membrane (Figure 15-36a, step **1**). In turn, activated phospholipase C cleaves PIP_2 into DAG, which remains associated with the membrane, and IP_3 , which freely diffuses in the cytosol (Figure 15-36a, step **2**). The two second messengers trigger separate downstream effects.

Ca^{2+} Release from the ER Triggered by IP_3 G protein-coupled receptors that activate phospholipase C induce an elevation in cytosolic Ca^{2+} even when Ca^{2+} ions are absent from the surrounding extracellular fluid. In this case, Ca^{2+} is released into the cytosol from the ER lumen through operation of the *IP_3 -gated Ca^{2+} channel* in the ER membrane, as depicted in Figure 15-36a (steps **3** and **4**). This large-channel protein is composed of four identical subunits, each of which contains an IP_3 -binding site in the N-terminal cytosolic domain. IP_3 binding induces opening of the channel, allowing Ca^{2+} to flow down its concentration gradient from the ER into the cytosol. When various phosphorylated inositols found in cells are added to preparations of ER vesicles, only IP_3 causes release of Ca^{2+} ions from the vesicles. This simple experiment demonstrates the specificity of the IP_3 effect.

FIGURE 15-35 Synthesis of second messengers DAG and IP₃ from phosphatidylinositol (PI). Each membrane-bound PI kinase places a phosphate (yellow circles) on a specific hydroxyl group on the inositol ring, producing the phosphorylated derivatives PIP and PIP₂.

Cleavage of PIP₂ by phospholipase C yields the two important second messengers DAG and IP₃. [See A. Tokar and L. C. Cantley, 1997, *Nature* 387:673, and C. L. Carpenter and L. C. Cantley, 1996, *Curr. Opin. Cell Biol.* 8:153.]

The IP₃-mediated rise in the cytosolic Ca²⁺ level is transient because Ca²⁺ pumps located in the plasma membrane and ER membrane actively transport Ca²⁺ from the cytosol to the cell exterior and ER lumen, respectively. Furthermore, within a second of its generation, the phosphate linked to the carbon-5 of IP₃ (see Figure 15-35) is hydrolyzed, yielding inositol 1,4-bisphosphate. This compound cannot bind to the IP₃-gated Ca²⁺ channel protein and thus does not stimulate Ca²⁺ release from the ER.

Without some means for replenishing depleted stores of intracellular Ca²⁺, a cell would soon be unable to increase the cytosolic Ca²⁺ level in response to hormone-induced IP₃. Patch-clamping studies (see Figure 11-22) have revealed that a plasma membrane Ca²⁺ channel, called the *store-operated channel*, opens in response to depletion of ER Ca²⁺ stores. Studies in which each potential channel protein was knocked down one at a time with shRNAs established the identity of this channel protein as Orai1. The Ca²⁺-sensing protein is STIM, a transmembrane protein in the endoplasmic reticulum membrane (Figure 15-36b). An EF hand, similar to that in calmodulin (see Figure 3-31), on the luminal side of the ER membrane binds Ca²⁺ when its level in the lumen is high. As endoplasmic reticulum Ca²⁺ stores are depleted, the STIM proteins lose their bound Ca²⁺, oligomerize, and in an unknown manner relocate to areas of the ER membrane near the plasma membrane (Figure 15-36b, right). There the STIM CAD domains bind to and trigger opening of Orai1, allowing influx of extracellular Ca²⁺. Combined overexpression of Orai and STIM in cultured cells leads to a marked

increase in Ca²⁺ influx, establishing that these two proteins are the key components of the store-operated Ca²⁺ pathway.

Continuous activation of certain G protein-coupled receptors induces rapid, repeated spikes in the level of cytosolic Ca²⁺. These bursts in cytosolic Ca²⁺ levels are caused by a complex interaction between the cytosolic Ca²⁺ concentration and the IP₃-gated Ca²⁺-channel protein. The submicromolar level of cytosolic Ca²⁺ in the resting state potentiates opening of these channels by IP₃, thus facilitating the rapid rise in cytosolic Ca²⁺ following hormone stimulation of the cell-surface G protein-coupled receptor. However, the higher cytosolic Ca²⁺ levels reached at the peak of the spike inhibit IP₃-induced release of Ca²⁺ from intracellular stores by decreasing the affinity of the Ca²⁺ channels for IP₃. As a result, the channels close, and the cytosolic Ca²⁺ level drops rapidly. Thus cytosolic Ca²⁺ is a feedback inhibitor of the protein, the IP₃-gated Ca²⁺ channel, that when open triggers elevation in cytosolic Ca²⁺. Calcium ion spikes occur in the pituitary gland cells that secrete luteinizing hormone (LH), which plays an important role in controlling ovulation and thus female fertility. LH secretion is induced by binding of luteinizing hormone-releasing hormone (LHRH) to its G protein-coupled receptors on these cells; LHRH binding induces repeated Ca²⁺ spikes. Each Ca²⁺ spike induces exocytosis of a few LH-containing secretory vesicles, presumably those close to the plasma membrane.

DAG Activation of Protein Kinase C After its formation by phospholipase C-catalyzed hydrolysis of PIP₂, DAG remains

FIGURE 15-36 IP₃/DAG pathway and the elevation of cytosolic Ca^{2+} . (a) Opening of endoplasmic reticulum Ca^{2+} channels. This pathway can be triggered by ligand binding to GPCRs that activate either the $\text{G}_{i/o}$ or $\text{G}_{12/13}$ alpha subunit leading to activation of phospholipase C (step 1). Cleavage of PIP_2 by phospholipase C yields IP_3 and DAG (step 2). After diffusing through the cytosol, IP_3 interacts with and opens Ca^{2+} channels in the membrane of the endoplasmic reticulum (step 3), causing release of stored Ca^{2+} ions into the cytosol (step 4). One of several cellular responses induced by a rise in cytosolic Ca^{2+} is recruitment of protein kinase C (PKC) to the plasma membrane (step 5), where it is activated by DAG (step 6). The activated membrane-associated kinase can phosphorylate various cellular enzymes and

receptors, thereby altering their activity (step 7). (b) Opening of plasma membrane Ca^{2+} channels. *Left:* In the resting cell, Ca^{2+} levels in the endoplasmic reticulum lumen are high, and Ca^{2+} ions (blue circles) bind to the EF hand domains of the transmembrane STIM1 proteins. *Right:* As endoplasmic reticulum Ca^{2+} stores are depleted and Ca^{2+} ions dissociate from the EF hands, STIM1s undergo oligomerization and relocalization to areas of the ER membrane near the plasma membrane. There the STIM1 CRAC-activating domains (CAD, green) bind to and trigger opening of Orai1, the store-operated Ca^{2+} channels in the plasma membrane, allowing influx of extracellular Ca^{2+} . [Adapted from J. W. Putney, 1999, *Proc. Nat'l. Acad. Sci. USA* **96**:14669; Y. Zhou, 2010, *Proc. Nat'l. Acad. Sci. USA* **107**:4896; and M. Cahalan, 2010, *Science* **130**:43.]

associated with the plasma membrane. The principal function of DAG is to activate a family of protein kinases collectively termed **protein kinase C (PKC)**. In the absence of hormone stimulation, protein kinase C is present as a soluble cytosolic protein that is catalytically inactive. A rise in the cytosolic Ca^{2+} level causes protein kinase C to translocate to the cytosolic leaflet of the plasma membrane, where it can interact with membrane-associated DAG (see Figure 15-36a, steps **5** and **6**). Activation of protein kinase C thus depends on an increase of both Ca^{2+} ions and DAG, suggesting an interaction between the two branches of the IP_3/DAG pathway.

The activation of protein kinase C in different cells results in a varied array of cellular responses, indicating that it plays a key role in many aspects of cellular growth and metabolism. In liver cells, for instance, protein kinase C helps regulate glycogen metabolism by phosphorylating and so inhibiting glycogen synthase. Protein kinase C also phosphorylates various transcription factors that in some cells activate genes necessary for cell division.

The Ca^{2+} -Calmodulin Complex Mediates Many Cellular Responses to External Signals

The ubiquitous small cytosolic protein calmodulin functions as a multipurpose switch protein that mediates many cellular effects of Ca^{2+} ions. Binding of Ca^{2+} to four sites on calmodulin yields a complex that interacts with and modulates the activity of many enzymes and other proteins (see Figure 3-31). Because four Ca^{2+} bind to calmodulin in a cooperative fashion, a small change in the level of cytosolic Ca^{2+} leads to a large change in the level of active calmodulin. One well-studied enzyme activated by the Ca^{2+} -calmodulin complex is myosin light-chain kinase, which regulates the activity of myosin and thus contraction in muscle cells (see Chapter 17). Another is cAMP phosphodiesterase, the enzyme that degrades cAMP to 5'-AMP and terminates its effects. This reaction thus links Ca^{2+} and cAMP, one of many examples in which two second-messenger-mediated pathways interact to fine-tune a cellular response.

In many cells, the rise in cytosolic Ca^{2+} following receptor signaling via phospholipase C-generated IP_3 leads to activation of specific transcription factors. In some cases, Ca^{2+} -calmodulin activates protein kinases that, in turn, phosphorylate transcription factors, thereby modifying their activity and regulating gene expression. In other cases, Ca^{2+} -calmodulin activates a phosphatase that removes phosphate groups from a transcription factor, thus activating it. An important example of this mechanism involves T cells of the immune system (see Chapter 23).

Signal-Induced Relaxation of Vascular Smooth Muscle Is Mediated by a Ca^{2+} -Nitric Oxide-cGMP-Activated Protein Kinase G Pathway

 Nitroglycerin has been used for over a century as a treatment for the intense chest pain of angina. It was known to slowly decompose in the body to *nitric oxide* (NO), which causes relaxation of the smooth muscle cells

surrounding the blood vessels that “feed” the heart muscle itself, thereby increasing the diameter of the blood vessels and increasing the flow of oxygen-bearing blood to the heart muscle. One of the most intriguing discoveries in modern medicine is that NO, a toxic gas found in car exhaust, is in fact a natural signaling molecule. ■

Definitive evidence for the role of NO in inducing relaxation of smooth muscle came from a set of experiments in which acetylcholine was added to experimental preparations of the smooth muscle cells that surround blood vessels. Direct application of acetylcholine to these cells caused them to contract, the expected effect of acetylcholine on these muscle cells. But addition of acetylcholine to the lumen of small isolated blood vessels caused the underlying smooth muscles to relax, not contract. Subsequent studies showed that in response to acetylcholine, the endothelial cells that line the lumen of blood vessels were releasing some substance that in turn triggered muscle-cell relaxation. That substance turned out to be NO.

We now know that endothelial cells contain a G_o protein-coupled receptor that binds acetylcholine and activates phospholipase C, leading to an increase in the level of cytosolic Ca^{2+} . After Ca^{2+} binds to calmodulin, the resulting complex stimulates the activity of NO synthase, an enzyme that catalyzes formation of NO from O_2 and the amino acid arginine. Because NO has a short half-life (2–30 seconds), it can diffuse only locally in tissues from its site of synthesis. In particular, NO diffuses from the endothelial cell into neighboring smooth muscle cells, where it triggers muscle relaxation (Figure 15-37).

The effect of NO on smooth muscle is mediated by the second messenger cGMP, which is formed by an intracellular NO receptor expressed by smooth muscle cells. Binding of NO to the heme group in this receptor leads to a conformational change that increases its intrinsic guanylyl cyclase activity, leading to a rise in the cytosolic cGMP level. Most of the effects of cGMP are mediated by a cGMP-dependent protein kinase, also known as **protein kinase G (PKG)**. In vascular smooth muscle, protein kinase G activates a signaling pathway that results in inhibition of the actin-myosin complex, relaxation of the cell, and so dilation of the blood vessel. In this case, cGMP acts indirectly via protein kinase G, whereas in rod cells cGMP acts directly by binding to and opening cation channels in the plasma membrane (see Figure 15-23).

Integration of Ca^{2+} and cAMP Second Messengers Regulates Glycogenolysis

Just as no cell lives in isolation, no intracellular signaling pathway functions alone. All cells constantly receive multiple signals from their environment, including changes in hormone levels, metabolites, and gases such as NO and oxygen; these signals must be integrated. The breakdown of glycogen to glucose (glycogenolysis) provides an excellent example of how cells can integrate their responses to more than one signal. As discussed in Section 15.5, epinephrine stimulation of muscle and liver cells leads to a rise in the second messenger cAMP,

FIGURE 15-37 The Ca^{2+} /nitric oxide (NO)/cGMP pathway and the relaxation of arterial smooth muscle. Nitric oxide is synthesized in endothelial cells in response to activation of acetylcholine GPCRs, phospholipase C, and the subsequent elevation in cytosolic Ca^{2+} (steps 1–4). NO diffuses locally through tissues and activates an intracellular NO receptor with guanylyl cyclase activity in nearby smooth muscle cells (5). The resulting rise in cGMP (6) activates protein kinase G (7), leading to relaxation of the muscle and thus vasodilation (8). PP_i = pyrophosphate. [See C. S. Lowenstein et al., 1994, *Ann. Intern. Med.* 120:227.]

which promotes glycogen breakdown (see Figure 15-31a). In both muscle and liver cells, other second messengers also produce the same cellular response.

In muscle cells, stimulation by nerve impulses causes the release of Ca^{2+} ions from the sarcoplasmic reticulum and an increase in the cytosolic Ca^{2+} concentration, which triggers muscle contraction. The rise in cytosolic Ca^{2+} also activates glycogen phosphorylase kinase (GPK), thereby stimulating the degradation of glycogen to glucose-1-phosphate, which fuels

prolonged contraction. Recall that phosphorylation by cAMP-dependent protein kinase A also activates glycogen phosphorylase kinase (see Figure 15-31). Thus this key regulatory enzyme in glycogenolysis is subject to both neural and hormonal regulation in muscle (Figure 15-38a).

In liver cells, hormone-induced activation of the effector protein phospholipase C also regulates glycogen breakdown by generating the second messengers DAG and IP₃. As we just learned, IP₃ induces an increase in cytosolic Ca^{2+} , which

FIGURE 15-38 Integrated regulation of glycogenolysis by Ca^{2+} and cAMP/PKA pathways. (a) Neuronal stimulation of striated muscle cells or epinephrine binding to β -adrenergic receptors on their surfaces leads to increased cytosolic concentration of the second messengers Ca^{2+} or cAMP, respectively. The key regulatory enzyme glycogen phosphorylase kinase (GPK) is activated by binding Ca^{2+} ions and by phosphorylation by cAMP-dependent protein kinase A (PKA). (b) In liver cells, hormonal stimulation of β -adrenergic receptors leads to increased cytosolic concentrations of cAMP and two other second messengers, diacylglycerol (DAG) and inositol 1,4,5-trisphosphate (IP₃). Enzymes are marked by white boxes. (+) = activation of enzyme activity; (–) = inhibition.

activates glycogen phosphorylase kinase as in muscle cells, leading to glycogen degradation. Moreover, the combined effect of DAG and increased Ca^{2+} activates protein kinase C (see Figure 15-36). This kinase can phosphorylate glycogen synthase, thereby inhibiting the enzyme and reducing the rate of glycogen synthesis. In this case, multiple intracellular signal transduction pathways are activated by the same signal (Figure 15-38b).

The dual regulation of glycogen phosphorylase kinase by Ca^{2+} and protein kinase A in both muscle and liver results from its multimeric subunit structure $(\alpha\beta\gamma\delta)_4$. The γ subunit is the catalytic enzyme; the regulatory α and β subunits, which are similar in structure, are phosphorylated by protein kinase A; and the δ subunit is the calcium sensor calmodulin. Glycogen phosphorylase kinase is maximally active when Ca^{2+} ions are bound to the calmodulin subunit and the α subunit has been phosphorylated by protein kinase A. In fact, binding of Ca^{2+} to the calmodulin subunit may be essential to the enzymatic activity of glycogen phosphorylase kinase. Phosphorylation of the α and also the β subunits by protein kinase A increases the affinity of the calmodulin subunit for Ca^{2+} , allowing Ca^{2+} ions to bind to the enzyme at the submicromolar Ca^{2+} concentrations found in noncontracting cells. Thus increases in the cytosolic concentration of Ca^{2+} or of cAMP (or both) induce incremental increases in the activity of glycogen phosphorylase kinase. As a result of the elevated level of cytosolic Ca^{2+} after neuronal stimulation of muscle cells, glycogen phosphorylase kinase will be active even if it is unphosphorylated; therefore glycogen can be hydrolyzed to fuel continued muscle contraction even in the absence of hormone stimulation.

KEY CONCEPTS of Section 15.6

G Protein–Coupled Receptors That Trigger Elevations in Cytosolic Ca^{2+}

- A small rise in cytosolic Ca^{2+} induces a variety of responses in different cells, including hormone secretion, contraction of muscle, and platelet aggregation (see Table 15-3).
- Many hormones bind GPCRs coupled to G proteins containing a $G_{\alpha o}$ or $G_{\alpha q}$ subunit. The effector protein activated by GTP-bound $G_{\alpha o}$ or $G_{\alpha q}$ is a phospholipase C enzyme.
- Phospholipase C cleaves a phospholipid known as PIP_2 , generating two second messengers: diffusible IP_3 and membrane-bound DAG (see Figure 15-35).
- IP_3 triggers opening of IP_3 -gated Ca^{2+} channels in the endoplasmic reticulum and elevation of cytosolic free Ca^{2+} . In response to elevated cytosolic Ca^{2+} , protein kinase C is recruited to the plasma membrane, where it is activated by DAG (see Figure 15-36a).
- Depletion of ER Ca^{2+} stores leads to opening of plasma membrane store-operated Ca^{2+} channels and an influx of Ca^{2+} from the extracellular medium (see Figure 15-36b).

- The Ca^{2+} -calmodulin complex regulates the activity of many different proteins, including cAMP phosphodiesterase and protein kinases and phosphatases that control the activity of various transcription factors.
- Stimulation of acetylcholine G protein–coupled receptors on endothelial cells induces an increase in cytosolic Ca^{2+} and subsequent synthesis of NO. After diffusing into surrounding smooth muscle cells, NO activates an intracellular guanylate cyclase to synthesize cGMP. The resulting increase in cGMP leads to activation of protein kinase G, which triggers a pathway resulting in muscle relaxation and vasodilation (see Figure 15-37).
- Glycogen breakdown and synthesis is coordinately regulated by the second messengers Ca^{2+} and cAMP, whose levels are regulated by neural and hormonal stimulation (see Figure 15-38).

Perspectives for the Future

In this chapter, we focused primarily on signal transduction pathways activated by individual G protein–coupled receptors. However, even these relatively simple pathways presage the more complex situation within living cells. Many G protein–coupled receptors form homodimers or heterodimers with other G protein–coupled receptors that bind ligands with different specificities and affinities. Much current research is focused on determining the functions of these dimeric receptors in the body.

With ~900 members in total, the G protein–coupled receptors represent the largest protein family in the human genome. Approximately half of these genes are thought to encode sensory receptors; of these the majority are in the olfactory system and bind odorants. Of the remaining G protein receptors, the natural ligand has not been identified for many so-called *orphan GPCRs*—that is, putative GPCRs without known cognate ligands. Many of these orphan receptors are likely to bind heretofore unidentified signaling molecules, including new peptide hormones. G protein–coupled receptors already comprise the targets of more than 30 percent of all approved therapeutic drugs, and therefore orphan GPCRs represent a fruitful resource for drug discovery by the pharmaceutical industry.

One approach that has proved fruitful in identifying ligands of orphan GPCRs involves expressing the receptor genes in transfected cells and using them as a reporter system to detect substances in tissue extracts that activate signal transduction pathways in these cells. This approach has already led to stunning insights into human behavior. One example is two novel peptides termed orexin-A and orexin-B (from the Greek *orexis*, meaning “appetite”) that were identified as the ligands for two orphan GPCRs. Further research showed that the *orexin* gene is expressed only in the hypothalamus, the part

of the brain that regulates feeding. Injection of orexin into the brain ventricles caused animals to eat more, and expression of the *orexin* gene increased markedly during fasting. Both of these findings are consistent with orexin's role in increasing appetite. Strikingly, mice deficient for orexins suffer from narcolepsy, a disorder characterized in humans by excessive daytime sleepiness (for mice, nighttime sleepiness). Moreover, very recent reports suggest that the orexin system is dysfunctional in a majority of human narcolepsy patients: orexin peptides cannot be detected in their cerebrospinal fluid (although there is no evidence of mutation in their *orexin* genes). These findings firmly link orexin neuropeptides and their receptors to both feeding behavior and sleep in both animals and humans.

More recently a new neuropeptide, neuropeptide S, was identified as the ligand for another previously orphaned GPCR. Researchers then showed that this neuropeptide modulates a number of biological functions, including anxiety, arousal, locomotion, and memory. One can only wonder about what other peptides and small-molecule hormones remain to be discovered and the insights that study of these will provide for our understanding of human metabolism, growth, and behavior.

Key Terms

adenylyl cyclase 692	IP ₃ /DAG pathway 708
agonist 682	kinase 677
antagonist 682	muscarinic acetylcholine receptors 693
arrestin 697	nitric oxide 711
autocrine 676	paracrine 675
β-adrenergic receptors 687	phosphatase 677
calmodulin 679	phospholipase C (PLC) 708
competition assay 682	protein kinase A (PKA) 701
cyclic AMP (cAMP) 679	protein kinase C (PKC) 711
desensitization 684	protein kinase G (PKG) 711
endocrine 675	rhodopsin 694
epinephrine 688	second messengers 674
glucagon 699	signal amplification 680
glycogenolysis 699	signal transduction 674
G protein-coupled receptors (GPCRs) 674	transducin 694
GTPase superfamily 678	trimeric G proteins 679
hormone 673	

Review the Concepts

1. What common features are shared by most cell signaling systems?
2. Signaling by soluble extracellular molecules can be classified as endocrine, paracrine, or autocrine. Describe how these three types of cellular signaling differ. Growth hormone is secreted from the pituitary, which is located at the

base of the brain and acts through growth hormone receptors located on the liver. Is this an example of endocrine, paracrine, or autocrine signaling? Why?

3. A ligand binds two different receptors with a K_d value of 10^{-7} M for receptor 1 and a K_d value of 10^{-9} M for receptor 2. For which receptor does the ligand show the greater affinity? Calculate the fraction of receptors that have a bound ligand ($[RL]/R_T$) in the case of receptor 1 and receptor 2 if the concentration of free ligand is 10^{-8} M.

4. To understand how a signaling pathway works, it often is useful to isolate the cell-surface receptor and to measure the activity of downstream effector proteins under different conditions. How could you use affinity chromatography to isolate a cell-surface receptor? With what technique could you measure the amount of activated G protein (the GTP-bound form) in ligand-stimulated cells? Describe the approach you would take.

5. How do seven transmembrane domain G protein-coupled receptors transmit a signal across the plasma membrane? In your answer, include the conformational changes that occur in the receptor in response to ligand binding.

6. Signal-transducing trimeric G proteins consist of three subunits designated α , β , and γ . The G_α subunit is a GTPase switch protein that cycles between active and inactive states depending on whether it is bound to GTP or to GDP. Review the steps for ligand-induced activation of effector proteins mediated by the trimeric G proteins. Suppose that you have isolated a mutant G_α subunit that has an increased GTPase activity. What effect would this mutation have on the G protein and the effector protein?

7. Explain how FRET could be used to monitor the association of $G_{\alpha s}$ and adenylyl cyclase following activation of the epinephrine receptor.

8. Which of the following steps amplify the epinephrine signal response in cells: receptor activation of G protein, G protein activation of adenylyl cyclase (AC), cAMP activation of PKA, or PKA phosphorylation of glycogen phosphorylase kinase (GPK)? Which change will have a greater effect on signal amplification: an increase in the number of epinephrine receptors or an increase in the number of $G_{\alpha s}$ proteins?

9. The cholera toxin, produced by the bacterium *Vibrio cholera*, causes a watery diarrhea in infected individuals. What is the molecular basis for this effect of cholera toxin?

10. Both rhodopsin in vision and the muscarinic acetylcholine receptor system in cardiac muscle are coupled to ion channels via G proteins. Describe the similarities and differences between these two systems.

11. Epinephrine binds to both β-adrenergic and α-adrenergic receptors. Describe the opposite actions on the effector protein, adenylyl cyclase, elicited by the binding of epinephrine to these two types of receptors. Describe the effect of adding an agonist or antagonist to a β-adrenergic receptor on the activity of adenylyl cyclase.

12. In liver and muscle, epinephrine stimulation of the cAMP pathway activates glycogen breakdown and inhibits

glycogen synthesis, whereas in adipose tissue, epinephrine activates hydrolysis of triglycerides and in other cells causes a diversity of other responses. What step in the cAMP signaling pathways in these cells specifies the cell response?

13. Continuous exposure of a $G_{\alpha s}$ protein-coupled receptor to its ligand leads to a phenomenon known as desensitization. Describe several molecular mechanisms for receptor desensitization. How can a receptor be reset to its original sensitized state? What effect would a mutant receptor lacking serine or threonine phosphorylation sites have on a cell?

14. What is the purpose of A kinase-associated proteins (AKAPs)? Describe how AKAPs work in heart muscle cells.

15. Inositol 1,4,5-trisphosphate (IP_3) and diacylglycerol (DAG) are second messenger molecules derived from the cleavage of the phosphatidylinositol 4,5-bisphosphate (PIP_2) by activated phospholipase C. Describe the role of IP_3 in causing a rise in cytosolic Ca^{2+} concentration. How do cells restore resting levels of cytosolic Ca^{2+} ? What is the principal function of DAG?

16. In Chapter 3, the K_d of calmodulin's EF hands for binding Ca^{2+} is given as $\sim 10^{-6}$ M. Many proteins have much higher affinities for their respective ligands. Why is the specific affinity of calmodulin important for Ca^{2+} signaling processes such as that initiated by production of IP_3 ?

17. Most of the short-term physiological responses of cells to cAMP are mediated by activation of PKA. cGMP is another common second messenger. What are the targets of cGMP in rod and smooth muscle cells?

Analyze the Data

1. Mutations in trimeric G proteins can cause many diseases in humans. Patients with acromegaly often have pituitary tumors that oversecrete growth hormone (GH). GH-releasing hormone (GHRH) stimulates GH release from the pituitary by binding to GHRH receptors and stimulating adenylyl cyclase. Researchers wanted to know whether mutations in $G_{\alpha s}$ played a role in this condition. Cloning and sequencing of the wild-type and mutant $G_{\alpha s}$ gene from normal individuals and patients with the pituitary tumors revealed a missense mutation in the $G_{\alpha s}$ gene sequence.

a. To investigate the effect of the mutation on $G_{\alpha s}$ activity, wild-type and mutant $G_{\alpha s}$ cDNAs were transfected into cells that lack the $G_{\alpha s}$ gene. These cells express a β_2 -adrenergic receptor, which can be activated by isoproterenol, a β_2 -adrenergic receptor agonist. Membranes were isolated from transfected cells and assayed for adenylyl cyclase activity in the presence of GTP or the hydrolysis-resistant GTP analog, GTP- γ S. From the figure below, what do you conclude about the effect of the mutation on $G_{\alpha s}$ activity in the presence of GTP alone compared with GTP- γ S alone or GTP plus isoproterenol (iso)?

b. In the transfected cells described in part (a), what would you predict would be the cAMP levels in cells transfected with the wild-type $G_{\alpha s}$ and the mutant $G_{\alpha s}$? What effect might this have on the cells?

c. To further characterize the molecular defect caused by this mutation, the intrinsic GTPase activity present in both wild-type and mutant $G_{\alpha s}$ was assayed. Assays for GTPase activity showed that the mutation reduced the $k_{cat-GTP}$ (catalysis rate constant for GTP hydrolysis) from a wild-type value of 4.1 min^{-1} to the mutant value of 0.1 min^{-1} . What do you conclude about the effect of the mutation on the GTPase activity present in the mutant $G_{\alpha s}$ subunit? How do these GTPase results explain the adenylyl cyclase results shown in part (a)?

2. The phosphorylation of a protein can influence its ability to interact with other proteins. These protein-protein interactions play a fundamental role in signal transduction pathways, and these interactions can be identified using numerous techniques, including fluorescence energy transfer (see Figure 15-18). Protein kinase A (PKA) has many substrates, one of which is glycogen phosphorylase kinase, which has a multimeric ($\alpha\beta\gamma\delta$)₄ structure containing two regulatory subunits (α and β), the catalytic γ subunit, and the calcium sensor δ subunit.

a. You are using fluorescence energy transfer to investigate PKA interactions with glycogen phosphorylase kinase and have cloned cDNA fusion constructs for three of its four different subunits (γ , β , and δ), all containing a fluorescent tag that when expressed excites at 480 nm and emits fluorescence at 535 nm. You also have cDNA encoding the catalytic domain of PKA fused to a tag that when expressed excites at 440 nm and emits at 480 nm. In the assay, if the PKA fusion protein interacts with one or more of the tagged glycogen phosphorylase kinase substrates, the transfer of energy from the PKA tag excites the tag on the substrate, causing it to emit fluorescence at 535 nm, and this can be detected.

Liver cells are transfected with the PKA fusion construct alone (control) or with the PKA fusion construct plus one of the three tagged glycogen phosphorylase kinase constructs and then later treated with epinephrine. The fluorescence emissions at 535 nm, resulting from the four different transfection experiments, repeated three different times, are shown in the graph below. Label the four bars on the graph, showing the emission of PKA by itself, PKA + the γ subunit,

PKA + the β subunit, and PKA + the δ subunit. Explain why there is only one major peak and why the values represented by the other three bars are not significantly different from each other.

b. Which combination above would produce emission at 535 nm if the experiment was repeated but instead of epinephrine you used dibutyryl-cAMP, which freely crosses the plasma membrane?

c. As described above, there are two regulatory subunits of glycogen phosphorylase, both of which are subjected to post-translational modifications. If the gene encoding the α subunit contained missense mutations whereby during translation all the serine, threonine and tyrosine residues were converted to some other amino acid, how would this affect the calcium sensor subunit of glycogen phosphorylase? The activity of glycogen phosphorylase in cells treated with epinephrine is shown in the following graph.

Draw what the activity would look like in comparison in epinephrine-treated cells expressing the α subunit containing the missense mutations described above.

3. cAMP is a second messenger that regulates many diverse cellular functions. In the intestinal lumen, cAMP is responsible for maintaining electrolyte and water balance. Certain bacterial toxins, including one produced by *Vibrio cholera*, can upset the levels of cAMP, leading to fatal dehydration.

a. Given what you know about the mechanism of *Vibrio cholera* toxin, label the graph below showing cAMP concentration in (1) normal intestinal epithelial cells treated with a GPCR agonist to activate $G_{\alpha s}$ and (2) cholera toxin-treated cells stimulated with the same GPCR agonist. Explain how you came to these conclusions.

b. Would you expect lower or higher levels of PKA in cells treated with cholera toxin? Explain how you came to these conclusions.

The Infancy of Signal Transduction—GTP Stimulation of cAMP Synthesis

M. Rodbell et al., 1971, *J. Biol. Chem.* **246**:1877

In the late 1960s, the study of hormone action blossomed following the discovery that cyclic adenosine monophosphate (cAMP) functioned as a second messenger, coupling the hormone-mediated activation of a receptor to a cellular response. In setting up an experimental system to investigate the hormone-induced synthesis of cAMP, Martin Rodbell discovered an important new player in intracellular signaling—guanosine triphosphate (GTP).

Background

The discovery of GTP's role in regulating signal transduction began with studies on how glucagon and other hormones send a signal across the plasma membrane that eventually evokes a cellular response. At the outset of Rodbell's studies, it was known that binding of glucagon to specific receptor proteins embedded in the membrane stimulates production of cAMP. The formation of cAMP from ATP is catalyzed by a membrane-bound enzyme called adenylyl cyclase. It had been proposed that the action of glucagon, and other cAMP-stimulating hormones, relied on additional molecular components that couple receptor activation to the production of cAMP. However, in studies with isolated fat-cell membranes known as "ghosts," Rodbell and his coworkers were unable to provide any further insight into how glucagon binding leads to an increase in production of cAMP. Rodbell then began a series of studies with a newly developed cell-free system, purified rat liver membranes, which retained both membrane-bound and membrane-associated proteins. These experiments eventually led to the finding that GTP is required for the glucagon-induced stimulation of adenylyl cyclase.

The Experiment

One of Rodbell's first goals was to characterize the binding of glucagon to the glucagon receptor in the cell-free rat liver membrane system. First, purified rat liver membranes were incubated with glucagon labeled with the radioactive isotope of iodine (^{125}I). Membranes were then separated from the unbound [^{125}I] glucagon by centrifugation. Once it was established that labeled glucagon would indeed bind to the purified rat liver cell membranes, the study went on to determine if this binding led directly to activation of adenylyl cyclase and production of cAMP in the purified rat liver cell membranes.

The production of cAMP in the cell-free system required the addition of ATP; the substrate for adenylyl cyclase, Mg^{2+} ; and an ATP-regenerating system consisting of creatine kinase and phosphocreatine. Surprisingly, when the glucagon-binding experiment was repeated in the presence of these additional factors, Rodbell observed a 50 percent decrease in glucagon binding. Full binding could be restored only when ATP was omitted from the reaction. This observation inspired an investigation of the effect of nucleoside triphosphates on the binding of glucagon to its receptor. It was shown that relatively high (i.e., millimolar) concentrations of not only ATP but also uridine triphosphate (UTP) and cytidine triphosphate (CTP) reduced the binding of labeled glucagon. In contrast, the reduction of glucagon binding in the presence of GTP occurred at far lower (micromolar) concentrations. Moreover, low concentrations of GTP were found to stimulate the dissociation of bound glucagon from the receptor. Taken together, these studies suggested that GTP alters the glucagon receptor in a manner that lowers its affinity for

glucagon. This decreased affinity both affects the ability of glucagon to bind to the receptor and encourages the dissociation of bound glucagon.

The observation that GTP was involved in the action of glucagon led to a second key question: Can GTP also exert an effect on adenylyl cyclase? Addressing this question experimentally required the addition of both ATP, as a substrate for adenylyl cyclase, and GTP, as the factor being examined, to the purified rat liver membranes. However, the previous study had shown that the concentration of ATP required as a substrate for adenylyl cyclase could affect glucagon binding. Might it also stimulate adenylyl cyclase? The concentration of ATP used in the experiment could not be reduced because ATP was readily hydrolyzed by ATPases present in the rat liver membrane. To get around this dilemma, Rodbell replaced ATP with an AMP analog, 5'-adenylylimidodiphosphate (AMP-PNP), which can be converted to cAMP by adenylyl cyclase yet is resistant to hydrolysis by membrane ATPases. The critical experiment now could be performed. Purified rat liver membranes were treated with glucagon both in the presence and absence of GTP, and the production of cAMP from AMP-PNP was measured. The addition of GTP clearly stimulated the production of cAMP when compared to the addition of glucagon alone (Figure 1), indicating that GTP affects not only the binding of glucagon to its receptor but also stimulates the activation of adenylyl cyclase.

Discussion

Two key factors led Rodbell and his colleagues to detect the role of GTP in signal transduction, whereas previous studies had failed to do so. First, by switching from fat-cell ghosts to the rat

FIGURE 1 Effect of GTP on glucagon-stimulated cAMP production from AMP-PNP by purified rat liver membranes. In the absence of GTP, glucagon stimulates cAMP formation about twofold over the basal level in the absence of added hormone. When GTP also is added, cAMP production increases another fivefold. [Adapted from M. Rodbell et al., 1971, *J. Biol. Chem.* **246**:1877.]

liver membrane system, the Rodbell researchers avoided contamination of their cell-free system with GTP, a problem associated with the procedure for isolating ghosts. Such contamination would mask the effects of GTP on glucagon binding and activation of adenylyl cyclase. Second, when ATP was first shown to influence glucagon binding, Rodbell did not simply accept the plausible explanation that ATP, the substrate for adenylyl cyclase, also affects binding of glucagon. Instead, he chose to test the effects on binding of the other common nucleoside triphosphates. Rodbell later noted that he knew commercial preparations of ATP often are contaminated with low concentra-

tions of other nucleoside triphosphates. The possibility of contamination suggested to him that small concentrations of GTP might exert large effects on glucagon binding and the stimulation of adenylyl cyclase.

This critical series of experiments stimulated a large number of studies on the role of GTP in hormone action, eventually leading to the discovery of G proteins, the GTP-binding proteins that couple certain receptors to the adenylyl cyclase. Subsequently, an enormous family of receptors that require G proteins to transduce their signals were identified in eukaryotes from yeast to humans. These G protein-coupled re-

ceptors are involved in the action of many hormones as well as in a number of other biological activities, including neurotransmission and the immune response. It is now known that binding of ligands to their cognate G protein-coupled receptors stimulates the associated G proteins to bind GTP. This binding causes transduction of a signal that stimulates adenylyl cyclase to produce cAMP and also desensitization of the receptor, which then releases its ligand. Both of these effects were observed in Rodbell's experiments on glucagon action. For these seminal observations, Rodbell was awarded the Nobel Prize in Physiology or Medicine in 1994.

Signaling Pathways That Control Gene Expression

Extracellular signals can have both short- and long-term effects on cells. Short-term effects are usually triggered by modification of existing proteins or enzymes, as we saw in Chapter 15. Many extracellular signals also affect gene expression and thus induce long-term changes in cell function. Long-term changes include alterations in cell division and differentiation, such as occur during development and cell fate determination. The body's production of red blood cells, white blood cells, and platelets in response to *cytokines* is a good example of signal-induced changes in gene expression that influence cell proliferation and differentiation. Changes in gene expression also enable differentiated cells to respond to their environment by changing their shape, metabolism, or movement. In immune system cells, for example, several hormones activate one type of transcription factor (NF- κ B) that ultimately impacts expression of more than 150 genes involved in the immune response to infection. Given the extensive role of gene transcription in

mediating critical aspects of development, metabolism, and movement, it is not surprising that mutations in such signaling pathways cause many human diseases, including cancer, diabetes, and immune disorders.

Transcription of genes is influenced by chromatin structure, epigenetic modifications to histones and other nuclear proteins, and the cell's complement of transcription factors and other proteins (see Chapter 7). These properties determine which genes the cell can potentially transcribe at any given time; we think of these properties as the cell's "memory," determined by its history and response to previous signals. Importantly, many key regulatory transcription factors are held in an inactive state in the cytosol or nucleus and become activated only in response to external signals, thus inducing expression of a set of genes that are specific to this cell type.

In this chapter, we explore the main signaling pathways that cells use to influence gene expression. In eukaryotes, there are about a dozen classes of highly conserved cell-surface

receptors, and these activate several types of highly conserved intracellular signal transduction pathways. Many of these pathways consist of multiple proteins, small intracellular molecules, and ions such as Ca^{2+} , which together form a complex cascade. Given this complexity, cell signaling can seem a daunting subject to learn for the first time; the many names and abbreviations of molecules found in each pathway can indeed be challenging. The subject repays careful study, however: when one becomes familiar with these pathways, one understands in a profound way the regulatory mechanisms that control a vast array of biological processes.

For simplicity, signal transduction pathways can be grouped into several basic types, based on the sequence of intracellular events. In one very common type of signal transduction pathway (Figure 16-1a), ligand binding to a receptor triggers activation of a receptor-associated kinase. This kinase may be an intrinsic part of the receptor protein or be tightly bound to the receptor. These kinases often directly phosphorylate and activate a variety of signal transduction proteins,

including transcription factors located in the cytosol (Figure 16-1a, **1**). Some receptor kinases also activate small GTP-binding “switch” proteins such as Ras (Figure 16-1a, **2**). Other receptors, mainly the seven spanning receptors introduced in Chapter 15, activate the larger GTP binding G_α proteins (Figure 16-1b). Both types of GTP-binding proteins can activate protein kinases that in turn phosphorylate multiple target proteins, including transcription factors. Many signal transduction pathways, such as those activated by Ras, involve several kinases in which one kinase phosphorylates and thus activates (or occasionally inhibits) the activity of another kinase.

In yet other signaling pathways, binding of a ligand to a receptor triggers disassembly of a multiprotein complex in the cytosol, releasing a transcription factor that then translocates into the nucleus (Figure 16-1c). Finally, in the last common type, proteolytic cleavage of an inhibitor or the receptor itself releases an active transcription factor, which then travels into the nucleus (Figure 16-1d). While every signaling pathway has its own subtleties and distinctions, nearly every one can be grouped into one of these basic types.

FIGURE 16-1 Several common cell-surface receptors and signal transduction pathways. (a) The cytosolic domains of many receptors contain protein kinase domains or are tightly associated with a cytosolic kinase; commonly the kinases are activated by ligand binding followed by receptor dimerization. Some of these kinases directly phosphorylate and activate transcription factors (**1**) or other signaling proteins. Many of these receptors also activate small GTP-binding “switch” proteins such as Ras (**2**). Many signal transduction pathways, such as those activated by Ras, involve several kinases in which one kinase phosphorylates and thus activates (or occasionally inhibits) the

activity of another kinase. Many of the kinases in these pathways phosphorylate multiple protein targets that can be different in different cells, including transcription factors. (b) Other receptors, mainly the seven-spanning receptors, activate the larger GTP-binding G_α proteins, which in turn activate specific kinases or other signaling proteins. (c) Several signaling pathways involve disassembly of a multiprotein complex in the cytosol, releasing a transcription factor that then translocates into the nucleus. (d) Some signaling pathways are irreversible; in many cases proteolytic cleavage of a receptor releases an active transcription factor.

The pathways we discuss in this chapter have been conserved throughout evolution and operate in much the same manner in flies, worms, and humans. The substantial homology exhibited among proteins in these pathways has enabled researchers to study them in a variety of experimental systems. For instance, the secreted signaling protein Hedgehog (Hh) and its receptor were first identified in *Drosophila* mutants. Subsequently, the human and mouse homologs of these proteins were cloned and shown to participate in a number of important signaling events during differentiation, resulting in the discovery that abnormal activation of the Hh pathway occurs in several human tumors. Such discoveries illustrate the importance of studying signaling pathways both genetically—in flies, mice, worms, yeasts, and other organisms—and biochemically.

No signaling pathway acts in isolation. Many cells respond to multiple types of hormones and other signaling molecules; some mammalian cells express ~100 different types of cell-surface receptors, each of which binds a different ligand. Since many genes are regulated by multiple transcription factors that in turn are activated or repressed by different intracellular signaling pathways, expression of any one gene can be regulated by multiple extracellular signals. Especially during early development, such “cross talk” between signaling pathways and the resultant sequential alterations in the pattern of gene expression eventually can become so extensive that the cell assumes a different developmental fate. In this chapter, we will see how multiple signaling pathways interact to regulate crucial aspects of metabolism, such as the level of glucose in the blood and the formation of adipose cells.

16.1 Receptors That Activate Protein Tyrosine Kinases

We begin with a discussion of two large classes of receptors that activate protein tyrosine kinases. Protein tyrosine kinases, of which there are about 90 in the human genome, phos-

phorylate specific tyrosine residues on target proteins, usually in the context of a specific linear sequence of amino acids in which the tyrosine is embedded. The phosphorylated target proteins can then activate one or more signaling pathways. These pathways are noteworthy because they regulate most aspects of cell proliferation, differentiation, survival, and metabolism.

There are two broad categories of receptors that activate tyrosine kinases: (1) those in which the tyrosine kinase enzyme is an intrinsic part of the receptor’s polypeptide chain (encoded by the same gene), called the **receptor tyrosine kinases (RTKs)**, and (2) those, such as **cytokine receptors**, in which the receptor and kinase are encoded by different genes yet bound tightly together. For cytokine receptors, the tightly bound kinase is known as a *JAK kinase*. Both classes of receptors activate similar intracellular signal transduction pathways, and we therefore consider them together in this section (Figure 16-2).

We will explore each of these important pathways in subsequent sections of the chapter. In this section, we focus on the receptors themselves, showing how ligand binding leads to kinase activation. We start with RTKs and then turn to cytokine receptors. After discussing how both types of receptors are activated, we explore some of the downstream molecules that are enlisted on activation. In the last part of the section, we discuss how signaling from RTKs and cytokine receptors is down-regulated.

Numerous Factors Regulating Cell Division and Metabolism Are Ligands for Receptor Tyrosine Kinases

The signaling molecules that activate RTKs are soluble or membrane-bound peptide or protein hormones, including many that were initially identified as growth factors for specific types of cells. These RTK ligands include many, such as nerve growth factor (NGF), platelet-derived growth factor (PDGF), fibroblast growth factor (FGF), and epidermal

FIGURE 16-2 Overview of signal transduction pathways triggered by receptors that activate protein tyrosine kinases. Both RTKs and cytokine receptors activate multiple signal transduction pathways that ultimately regulate transcription of genes. (a) In the most direct pathway, mainly employed by cytokine receptors, a STAT transcription factor binds to the activated receptor, becomes phosphorylated, moves to the nucleus, and directly activates transcription (see Section 16.1).

(b) Binding of one type of adapter protein (GRB2 or Shc) to an activated receptor leads to activation of the Ras/MAP kinase pathway (see Section 16.2). (c, d) Two phosphoinositide pathways are triggered by recruitment of phospholipase C_γ and PI-3 kinase to the membrane (see Section 16.3). Elevated levels of Ca^{2+} and activated protein kinase B modulate the activity of transcription factors as well as of cytosolic proteins that are involved in metabolic pathways or cell movement or shape.

growth factor (EGF), that stimulate proliferation and differentiation of specific cell types. Others, such as insulin, regulate expression of multiple genes that control sugar and lipid metabolism in liver, muscle, and adipose (fat) cells. Many RTKs and their ligands were identified in studies of human cancers associated with mutant forms of growth-factor receptors that stimulate proliferation even in the absence of growth factor. The mutation “tricks” the receptor into behaving as though the ligand is present at all times and so the receptor is constantly in an active state (*constitutively active*). Other RTKs have been uncovered during analysis of developmental mutations that lead to blocks in differentiation of certain cell types in *C. elegans*, *Drosophila*, and the mouse.

Binding of Ligand Promotes Dimerization of an RTK and Leads to Activation of Its Intrinsic Kinase

All RTKs have three essential components: an extracellular domain containing a ligand-binding site, a single hydrophobic transmembrane α helix, and a cytosolic segment that includes a domain with protein tyrosine kinase activity (Figure 16-3). Most RTKs are monomeric, and ligand binding to the extracellular domain induces formation of receptor dimers. The formation of functional dimers is a necessary step in activation of all RTKs. We term this process of two (or more) receptors joining together “activation by receptor oligomerization.” Such oligomerization of cell-surface receptors is, we will see, a common mechanism for activating multiple types of receptors.

RTK activation can be summarized as follows: in the resting, unstimulated (no ligand bound) state, the intrinsic kinase

activity of an RTK is very low (see Figure 16-3, step **1**). Like most other kinases, RTKs contain a flexible domain termed the *activation lip*. In the resting state, the activation lip is unphosphorylated and assumes a conformation that blocks kinase activity. In some receptors (e.g., the insulin receptor), it prevents binding of ATP. In others, (e.g., the FGF receptor), it prevents binding of substrate. Binding of ligand causes a conformational change that promotes dimerization of the extracellular domains of RTKs, which brings their transmembrane segments—and therefore their cytosolic domains—close together. The kinase in one subunit then phosphorylates a particular tyrosine residue in the activation lip in the other subunit (Figure 16-3, step **2**). This phosphorylation leads to a conformational change in the activation lip that unblocks and thus activates kinase activity by reducing the K_m for ATP or the substrate to be phosphorylated. The resulting enhanced kinase activity can then phosphorylate additional tyrosine residues in the cytosolic domain of the receptor (Figure 16-3, step **3**) as well as phosphorylate other target proteins, leading to intracellular signaling.

Although dimerization is a necessary step in the activation of all RTKs, functional dimers can be formed in multiple ways. Binding of EGF, for example, to its RTK triggers a conformational change in the receptor extracellular domain so that it “clamps” down on the ligand. This action pushes out a loop located between the two EGF-binding domains, and interactions between the two extended (“activated”) loop segments allow formation of the functional receptor dimer (Figure 16-4). In other cases, such as the fibroblast growth factor (FGF) receptor, each of the two ligands binds simultaneously to the extracellular domains of two receptor subunits. FGF also binds tightly to heparan sulfate, a negatively charged polysaccharide component of some cell-surface

FIGURE 16-3 General structure and activation of receptor tyrosine kinases (RTKs). The cytosolic domain of RTKs contains an intrinsic protein tyrosine kinase catalytic site. In the absence of ligand (**1**), RTKs generally exist as monomers with poorly active kinases. Ligand binding causes a conformational change that promotes formation of a functional dimeric receptor, bringing together two poorly active kinases

that then phosphorylate each other on a tyrosine residue in the activation lip (**2**). Phosphorylation causes the lip to move out of the kinase catalytic site, thus increasing the ability of ATP and the protein substrate to bind. The activated kinase then phosphorylates several tyrosine residues in the receptor’s cytosolic domain (**3**). The resulting phosphotyrosines function as docking sites for various signal transduction proteins.

FIGURE 16-4 Ligand-induced dimerization of HER1, a human receptor for epidermal growth factor (EGF). (a) Schematic depiction of the extracellular and transmembrane domains of HER1, which is a receptor tyrosine kinase. Binding of one EGF molecule to a monomeric receptor causes an alteration in the structure of a loop between the two EGF-binding domains. Dimerization of two identical ligand-bound receptor monomers in the plane of the membrane occurs primarily through interactions between the two “activated” loop segments. (b) Structure of the dimeric HER1 protein bound to transforming growth factor α (TGF- α), a member of the EGF family. The receptor’s extracellular domains are shown in blue; the transmembrane domain is shown in red as an α helix, but its structure is not known in detail. The two smaller TGF α molecules are colored green. Note the interaction between the “activated” loop segments in the two receptor monomers. [Part (a) adapted from J. Schlessinger, 2002, *Cell* 110:669; part (b) from T. Garrett et al., 2002, *Cell* 110:763.]

proteins and of the extracellular matrix (see Chapter 20); this association enhances ligand binding and formation of a dimeric receptor–ligand complex (Figure 16-5). The participation of the heparan sulfate is essential for efficient receptor activation. The ligands for some RTKs are dimeric, and their binding brings two receptor monomers together directly. Yet other RTKs, such as the insulin receptor, form disulfide-linked dimers even in the absence of hormone; binding of ligand to this type of RTK alters its conformation in such a way that the receptor kinase becomes activated. This last example highlights that simply having two receptor monomers in close contact is not sufficient for receptor activation—the

FIGURE 16-5 Structure of the fibroblast growth factor (FGF) receptor, stabilized by heparan sulfate. Shown here are side and top-down views of the complex comprising the extracellular domains of two FGF receptor (FGFR) monomers (green and blue), two bound FGF molecules (white), and two short heparan sulfate chains (purple), which bind tightly to FGF. (a) In the side view, the upper domain of one receptor monomer (blue) is seen situated behind that of the other (green); the plane of the plasma membrane is at the bottom. A small segment of the extracellular domain whose structure is not known connects to the membrane-spanning α -helical segment of each of the two receptor monomers (not shown) that protrude downward into the membrane. (b) In the top view, the heparan sulfate chains are seen threading between and making numerous contacts with the upper domains of both receptor monomers. These interactions promote binding of the ligand to the receptor and receptor dimerization. [Adapted from J. Schlessinger et al., 2000, *Mol. Cell* 6:743.]

FIGURE 16-6 Activation of EGF receptor by EGF results in the formation of an asymmetric kinase domain dimer. In the inactive, monomeric state (1) the unstructured segment of the juxtamembrane domain (JM-B; green) binds to the upper, or N lobe of the kinase domain, causing a conformational change that positions the activation lip in the kinase active site and thus inhibits kinase activation. Receptor dimerization generates an asymmetric kinase dimer (2) such that the

activator kinase binds the juxtamembrane segment of the receiver kinase, causing a conformational change that removes the activation lip from the kinase site of the receiver kinase, activating its kinase activity. (3) The active kinase then phosphorylates tyrosine residues (yellow circles) in the C-terminal segments of the receptor cytosolic domain. [After N. Jura et al., 2009, *Cell* 137:1293.]

proper conformational changes must accompany receptor dimerization to lead to tyrosine kinase activation. Once an RTK is locked into a functional dimeric state, its associated tyrosine kinase becomes activated.

Exactly how dimerization leads to kinase activation is understood only for members of the EGF receptor family and was uncovered through structural studies of the receptor cytosolic domains in both active and inactive states. The kinase domains are separated from the transmembrane segment by a so-called juxtamembrane segment, whose two parts are colored red and green in Figure 16-6. In the inactive, monomeric state, one part of the juxtamembrane segment binds to the upper, or N, lobe of the adjacent kinase domain in the same molecule. This causes a conformational change such that the activation lip is localized in the active site of the kinase, blocking its activity. In this way the kinase is maintained in the “off” state (Figure 16-6, step 1). Receptor dimerization generates an asymmetric kinase dimer (Figure 16-6, step 2) such that one kinase domain—termed the activator—binds the juxtamembrane segment of the second kinase domain—the receiver. This changes the conformation of the N lobe of the receiver, causing the activation lip to move out of the kinase active site and allowing the kinase to function (step 3). In a sense, an RTK can be thought of as an allosteric enzyme whose active site is inside the cell and whose allosteric effector—the ligand—binds to an extracellular regulatory site on the enzyme. Evolution has produced many variations on the theme of this simple ligand-RTK mechanism, as is exemplified by the families of EGF ligands and receptors discussed below.

Homo- and Hetero-oligomers of Epidermal Growth Factor Receptors Bind Members of the Epidermal Growth Factor Superfamily

Four receptor tyrosine kinases (RTKs) participate in signaling by the many members of the epidermal growth factor (EGF) family of signaling molecules. In humans, the four members of the **HER** (*human epidermal growth factor receptor*) family are denoted HER1, 2, 3, and 4. HER1 directly binds three EGF family members: EGF, heparin-binding EGF (HB-EGF), and tumor-derived growth factor alpha (TGF- α). Binding of any of these ligands to the extracellular domain of a HER1 monomer leads to homodimerization of the HER1 extracellular domain (Figure 16-7).

Two other members of the EGF family, neuregulins 1 and 2 (NRG1 and NRG2), bind to both HER3 and HER4; HB-EGF also binds to HER4. Importantly, HER2 does not directly bind a ligand but exists on the membrane in a preactivated conformation with the loop segment protruding outward and the ligand-binding domains in close proximity (Figure 16-7a). HER2, however, cannot form homodimers. It can signal only by forming heterocomplexes with ligand-bound HER1, HER3, or HER4. Thus it facilitates signaling by all EGF family members (Figure 16-7b); an increase in HER2 on the cell surface will make the cell more sensitive to signaling by many EGF family members because the rate at which the signaling heterodimers are formed after ligand binding will be enhanced. Even though HER3 lacks a functional kinase domain, it can still participate in signaling;

FIGURE 16-7 The HER family of receptors and their ligands.

Humans express four receptor tyrosine kinases—denoted HER1, 2, 3, and 4—that bind epidermal growth factor (EGF) and other EGF family members. (a) As shown, the HER proteins differentially bind EGF, heparin-binding EGF (HB-EGF), tumor-derived growth factor alpha (TGF- α), and neuregulins 1 and 2 (NRG1 and NRG2). Note that HER2, which does not directly bind a ligand, exists in the plasma surface membrane in a preactivated state indicated by a red hook.

(b) Ligand-bound HER1 can form activated homodimers bound together by loop segments (red hooks), as detailed in Figure 16-4. HER2 forms heterodimers with ligand-bound HER1, HER3, and HER4 and facilitates signaling by all EGF family members. HER3 has a very poorly active kinase domain and can signal only when complexed with HER2. [After N. E. Hynes and H. A. Lane, 2005, *Nature Rev. Cancer* 5:341 (erratum in *Nature Rev. Cancer* 5:580), and A. B. Singh and R. C. Harris, 2005, *Cell Signal* 17(Oct.):1183.]

after binding a ligand, it dimerizes with HER2 and becomes phosphorylated by the HER2 kinase. This activates downstream signal transduction pathways as indicated below.

 Understanding the HERs has helped explain why a particular form of breast cancer is so dangerous and has led to an important drug therapy. Breast cancer can involve the abnormal growth of breast epithelial cells. Normal epithelial cells express a small amount of HER2 protein on their plasma membranes in a tissue-specific pattern, and they do not grow inappropriately. In tumor cells, errors in DNA replication often result in formation of multiple copies of a given gene on a single chromosome, an alteration known as gene amplification (see Chapter 24). Amplification of the *HER2*

gene occurs in approximately 25 percent of breast cancers, resulting in overexpression of HER2 protein in the tumor cells. Breast cancer patients with HER2 overexpression have a worse prognosis, including shortened survival, than do patients without this abnormality. As Figure 16-7 emphasizes, overexpression of HER2 makes the tumor cells sensitive to growth stimulation by low levels of any member of the EGF family of growth factors, levels that would not stimulate proliferation of cells with normal HER2 levels. Discovery of the role of HER2 overexpression in certain breast cancers led researchers to develop monoclonal antibodies specific for the HER2 protein. These have proved to be effective therapies for those breast cancer patients in which HER2 is overexpressed, reducing recurrence by about 50 percent in these patients. ■

FIGURE 16-8 Erythropoietin and formation of red blood cells (erythrocytes). Erythroid progenitor cells, called colony-forming units erythroid (CFU-E), are derived from hematopoietic stem cells, which also give rise to progenitors of other blood cell types (see Figure 21-18). In the absence of erythropoietin (Epo), CFU-E cells undergo apoptosis. Binding of Epo to its receptors on a CFU-E induces transcription of several genes whose encoded proteins prevent programmed cell death (apoptosis), allowing the cell to survive. Other Epo-induced proteins trigger the developmental program of three to five terminal cell divisions. If CFU-E cells are cultured with Epo in a semisolid medium (e.g., containing methylcellulose), daughter cells cannot move away, and thus each CFU-E produces a colony of 30–100 erythroid cells; hence its name. [See M. Socolovsky et al., 2001, *Blood* 98:3261.]

Cytokines Influence Development of Many Cell Types

The cytokines form a family of relatively small, secreted signaling molecules (generally containing about 160 amino acids) that control growth and differentiation of specific types of cells. During pregnancy, for example, the cytokine *prolactin* induces epithelial cells lining the immature ductules of the mammary gland to differentiate into the acinar cells that produce milk proteins and secrete them into the ducts. Other cytokines, the *interleukins*, are essential for proliferation and

functioning of T cells and antibody-producing B cells of the immune system. Another family of cytokines, the *interferons*, are produced and secreted by certain cell types following virus infection and act on nearby cells to induce enzymes that render these cells more resistant to virus infection.

Many cytokines induce formation of important types of blood cells. All blood cells are derived from a common stem cell, which forms a series of progenitor cells that then differentiate into the mature blood cells (Figure 16-8; see also Figure 21-18). For instance, the cytokine granulocyte colony stimulating factor (G-CSF) induces a granulocyte progenitor cell in the bone marrow to divide several times and then differentiate into granulocytes, the type of white blood cell that inactivates bacteria and other pathogens. Another cytokine, **erythropoietin (Epo)**, triggers production of erythrocytes (red blood cells) by inducing the proliferation and differentiation of erythroid progenitor cells in the bone marrow (Figure 16-8). Erythropoietin is synthesized by certain kidney cells. A drop in blood oxygen, such as caused by loss of blood from a large wound, signifies a lower than optimal level of erythrocytes, whose major function is to transport oxygen complexed to hemoglobin. By means of the oxygen-sensitive transcription factor HIF-1 α , the kidney cells respond to low oxygen by synthesizing more erythropoietin and secreting it into the blood. As the level of erythropoietin rises, more and more erythroid progenitors are induced to divide and differentiate; each progenitor produces ~50 or so erythrocytes in a period of only a few days. In this way, the body can respond to the loss of blood by accelerating the production of erythrocytes. Both Epo and G-CSF are produced commercially by recombinant expression in cultured mammalian cells. Patients with kidney disease, especially those undergoing dialysis, frequently are anemic (have a low red blood cell count) and therefore are treated with recombinant Epo to boost red cell levels. Epo and G-CSF are used as adjuncts to certain cancer therapies since many cancer treatments affect the bone marrow and reduce production of red cells and granulocytes. ■

Binding of a Cytokine to Its Receptor Activates a Tightly Bound JAK Protein Tyrosine Kinase

All cytokines evolved from a common ancestral protein and have a similar tertiary structure consisting of four long conserved α helices folded together. Likewise, the various cytokine receptors undoubtedly evolved from a single common ancestor since all cytokine receptors have similar structures. Their extracellular domains are constructed of two subdomains, each of which contains seven conserved β strands folded together in a characteristic fashion. The interaction of one erythropoietin molecule with two identical erythropoietin receptor (EpoR) proteins, depicted in Figure 16-9, exemplifies the binding of a cytokine to its receptor.

Cytokine receptors do not possess intrinsic enzymatic activity. Rather, a **JAK kinase** is tightly bound to the cytosolic

FIGURE 16-9 Structure of erythropoietin bound to an erythropoietin receptor. Erythropoietin (Epo) contains four conserved long α helices that are folded in a particular arrangement. The activated erythropoietin receptor (EpoR) is a dimer of identical subunits; the extracellular domain of each monomer is constructed of two subdomains each containing seven conserved β strands folded in a characteristic fashion. Side chains of residues on two of the α helices in Epo, termed site 1, contact loops on one EpoR monomer, while residues on the two other Epo α helices, site 2, bind to the same loop segments in a second receptor monomer, thereby stabilizing the dimeric receptor in a specific conformation. The structures of other cytokines and their receptors are similar to Epo and EpoR. [Courtesy Lucy Zhang; adapted from R. S. Syed et al., 1998, *Nature* **395**:511, and L. Zhang et al., 2009, *Mol. Cell* **33**:266–274.]

domain of all cytokine receptors (Figure 16-10). The four members of the JAK family of kinases contain an N-terminal receptor-binding domain, a C-terminal kinase domain that is normally poorly active catalytically, and a middle domain that regulates kinase activity by an unknown mechanism. (JAKs are so named because when they were cloned and characterized, their function was unknown; they were termed just *another kinase*.) As in RTKs, this kinase becomes activated after ligand binding and receptor dimerization (Figure 16-10, step 1).

As a result of receptor dimerization, the associated JAKs are brought close enough together so that one can phosphory-

late the other on a critical tyrosine in the activation lip (Figure 16-10, step 2). As with many other kinases, phosphorylation of the activation lip leads to a conformational change that enhances the affinity for ATP or the substrate to be phosphorylated, thereby increasing kinase activity (Figure 16-10, step 3). One piece of evidence for this activation mechanism comes from study of a mutant JAK2 in which the critical tyrosine is mutated to phenylalanine. The mutant JAK2 binds normally to the EpoR but cannot be phosphorylated and is catalytically inactive. In erythroid cells, expression of this mutant JAK2 in greater than normal amounts totally blocks EpoR signaling because the mutant JAK2 binds to the majority of cytokine receptors, preventing binding and functioning of the wild-type JAK2 protein. This type of mutation, referred to as **dominant-negative**, causes loss of function even in cells that carry copies of the wild-type gene because the mutant protein prevents the normal protein from functioning (see Chapter 5).

FIGURE 16-10 General structure and activation of cytokine receptors. The cytosolic domain of cytokine receptors binds tightly and irreversibly to a JAK protein tyrosine kinase. In the absence of ligand (1), the receptors form a homodimer but the JAK kinases are poorly active. Ligand binding causes a conformational change that

brings together the associated JAK kinase domains, which then phosphorylate each other on a tyrosine residue in the activation lip (2). Downstream signaling (3) then proceeds in a manner similar to that from receptor tyrosine kinases.

Phosphotyrosine Residues Are Binding Surfaces for Multiple Proteins with Conserved Domains

Once the RTK kinases or JAK kinases become activated, they first phosphorylate several tyrosine residues on the cytosolic domain of the receptor (see Figures 16-3 and 16-10). Several of these phosphotyrosine residues then serve as binding sites for proteins that have conserved phosphotyrosine-binding domains. One such phosphotyrosine-binding domain is called the *SH2 domain*. The SH2 domain derived its full name, the *Src homology 2 domain*, from its homology with a region in the prototypical *Src* cytosolic tyrosine kinase encoded by the *src* gene. (*Src* is an acronym for *sarcoma*, and a mutant form of the cellular *src* gene was found in chickens with sarcomas, as Chapter 24 details.) The three-dimensional structures of SH2 domains in different proteins are very similar, but each binds to a distinct sequence of amino acids surrounding a phosphotyrosine residue. The unique amino acid sequence of each SH2 domain determines the specific phosphotyrosine residues it binds (Figure 16-11). Variations in the hydrophobic socket in the SH2 domains of different signal transduction proteins allow them to bind to phosphotyrosines adjacent to different sequences, accounting for differences in their binding partners. The SH2 domain of the *Src* tyrosine kinase, for example, binds strongly to any peptide containing a critical four-residue core sequence: phosphotyrosine–glutamic acid–glutamic acid–isoleucine (Figure 16-11). These four amino acids make intimate contact with the peptide-binding site in the *Src* SH2 domain. Binding resembles the insertion of a two-pronged “plug”—the phosphotyrosine and isoleucine side chains of

the peptide—into a two-pronged “socket” in the SH2 domain. The two glutamic acids fit snugly onto the surface of the SH2 domain between the phosphotyrosine socket and the hydrophobic socket that accepts the isoleucine residue. This specificity plays an important role in determining which signal transduction proteins bind to which receptors and so what pathways are activated.

There are other small protein domains besides SH2 that can recognize and bind to phosphotyrosine-containing peptides. One such domain is called the *PTB (phosphotyrosine-binding) domain*. PTB domains are often found on so-called *multidocking* proteins, which serve as docking sites for other signal transduction proteins. For example, when several RTKs (e.g., the insulin receptor) and cytokine receptors (e.g., the IL-4 receptor) are activated and tyrosine phosphorylated, they bind a multidocking protein called IRS-1 (discovered because it is an insulin receptor substrate) (Figure 16-12). The activated receptor then phosphorylates the bound docking protein, forming many phosphotyrosines that in turn serve as docking sites for SH2-containing signaling proteins. Some of these proteins in turn may also be phosphorylated by the activated receptor, and thus these multidocking proteins expand the number of intracellular signaling pathways that can be activated by the receptor.

SH2 Domains in Action: JAK Kinases Activate STAT Transcription Factors

To illustrate how binding of SH2 domains to specific phosphotyrosine residues induces specific signaling pathways, here

FIGURE 16-11 Surface model of an SH2 domain bound to a phosphotyrosine-containing peptide. The peptide bound by this SH2 domain from *Src* tyrosine kinase (blue backbone with red oxygen atoms) is shown in stick form. The SH2 domain binds strongly to shorttarget peptides containing a critical four-residue core sequence: phosphotyrosine (Tyr0 and OPO_3^-)–glutamic acid (Glu1)–

glutamic acid (Glu2)–isoleucine (Ile3). Binding resembles the insertion of a two-pronged “plug”—the phosphotyrosine and isoleucine side chains of the peptide—into a two-pronged “socket” in the SH2 domain. The two glutamate residues are bound to sites on the surface of the SH2 domain between the two sockets. [See G. Waksman et al., 1993, *Cell* 72:779.]

FIGURE 16-12 Recruitment of intracellular signal transduction proteins to the cell membrane by binding to phosphotyrosine residues in receptors or receptor-associated proteins. Cytosolic proteins with SH2 (purple) or PTB (maroon) domains can bind to specific phosphotyrosine residues in activated RTKs (shown here) or cytokine receptors. In some cases, these signal transduction proteins then are phosphorylated by the receptor's intrinsic or associated protein tyrosine kinase, enhancing their activity. Certain RTKs and cytokine receptors utilize multidocking proteins such as IRS-1 to increase the number of signaling proteins that are recruited and activated. Subsequent phosphorylation of a receptor-bound IRS-1 by the receptor kinase creates additional docking sites for SH2-containing signaling proteins.

we'll discuss the straightforward mechanism by which all JAK kinases and some RTKs directly activate members of the STAT family of transcription factors. All STAT proteins contain an N-terminal DNA-binding domain, an SH2 domain that binds to one or more specific phosphotyrosines in a cytokine receptor's cytosolic domain, and a C-terminal domain with a critical tyrosine residue. Once a monomeric STAT is bound to the receptor via its SH2 domain, the C-terminal tyrosine is phosphorylated by an associated JAK kinase (Figure 16-13a). This arrangement ensures that in a particular cell, only those STAT proteins with an SH2 domain that can bind to a particular receptor protein will be activated and only when that receptor is activated. The erythropoietin receptor, for example, activates STAT5 but not STATs 1, 2, 3, or 4; these are activated by other receptors. A phosphorylated STAT dissociates spontaneously from the receptor, and two phosphorylated STAT proteins form a dimer in which the SH2 domain on each binds to the phosphotyrosine in the other. Because dimerization involves conformational changes that expose the nuclear-localization signal (NLS), STAT dimers move into the nucleus, where they bind to specific enhancers (DNA regulatory sequences) controlling target genes (Figure 16-13b) and thus alter gene expression.

A given STAT can activate different genes in different cells depending on the "cell memory" discussed in the chap-

ter introduction. Because different cell types have unique complements of transcription factors and unique epigenetic modifications on their chromatin, the genes that are available to be activated by any STAT are also different. For example, in mammary gland cells STAT5, the same STAT activated by the Epo receptor in erythroid cells, becomes activated following prolactin binding to the prolactin receptor and induces transcription of genes encoding certain milk proteins. In contrast, when STAT5 becomes activated in erythroid progenitor cells following binding of Epo to the Epo receptor, it induces transcription of the *Bcl-x_L* gene. *Bcl-x_L* prevents the programmed cell death, or apoptosis, of these progenitors, allowing them to proliferate and differentiate into red blood cells. Here we have a case of different cytokine receptors in different cells activating the same intermediate signaling molecule, STAT5, yet leading to the activation of different genes. Combinatorial diversity allows a relatively limited set of signaling pathways to control a vast array of cellular activities.

Multiple Mechanisms Down-Regulate Signaling from RTKs and Cytokine Receptors

In the last chapter, we saw several ways in which signaling from G protein-coupled receptors is terminated. For instance, phosphorylation of receptors and downstream signaling proteins suppress signaling and this suppression can be reversed by the controlled action of phosphatases. Here we discuss several mechanisms by which RTK and cytokine receptor signaling is regulated.

Receptor-Mediated Endocytosis Prolonged treatment of cells with ligand often reduces the number of available cell-surface receptors such that the cells will have a less robust response to exposure to a given concentration of ligand than they did before the treatment. This desensitization response helps prevent inappropriately prolonged receptor activity. In the absence of epidermal growth factor (EGF), for instance, cell-surface HER1 receptors for this ligand are relatively long-lived, with an average half-life of 10 to 15 hours. Unbound receptors are internalized via clathrin-coated pits into endosomes at a relatively slow rate, on average once every 30 minutes, and often are returned rapidly to the plasma membrane so that there is little reduction in total surface receptor numbers. Following binding of an EGF ligand, the rate of endocytosis of HER1 is increased ~10-fold, and only a fraction of the internalized receptors return to the plasma membrane; the rest are degraded in lysosomes. Each time a HER1-EGF complex is internalized, via the process termed **receptor-mediated endocytosis** (see Figure 14-29), the receptor has about a 20 to 80 percent chance of being degraded, depending on the cell type. Exposure of a fibroblast cell to high levels of EGF for several hours induces several rounds of endocytosis, resulting in degradation of most cell-surface receptor molecules and thus a reduction in the cell's sensitivity to EGF. In this way, prolonged treatment with a given concentration of EGF desensitizes the cell to that level of hormone, though the cell may respond if the level of EGF is increased.

FIGURE 16-13 Activation and structure of STAT proteins.

(a) Phosphorylation and dimerization of STAT proteins. **Step 1:** Following activation of a cytokine receptor (see Figure 16-10), an inactive monomeric STAT transcription factor binds to a phosphotyrosine in the receptor, bringing the STAT close to the active JAK associated with the receptor. The JAK then phosphorylates the C-terminal tyrosine in the STAT. **Steps 2 and 3:** Phosphorylated STATs spontaneously dissociate from the receptor and spontaneously dimerize. Because the STAT homodimer has two phosphotyrosine-SH₂ domain interactions, whereas the receptor-STAT complex is stabilized by only one such interaction, phosphorylated STATs tend not to rebind to the receptor. **Step 4:** The STAT dimer moves into the nucleus, where it can bind to promoter sequences and activate transcription of target genes. (b) Ribbon diagram of the STAT1 dimer bound to DNA (black). The STAT1 dimer forms a C-shaped clamp around DNA that is stabilized by reciprocal and highly specific interactions between the SH₂ domain (purple) of one monomer and the phosphorylated tyrosine residue (yellow with red oxygens) on the C-terminal segment of the other. The phosphotyrosine-binding site of the SH₂ domain in each monomer is coupled structurally to the DNA-binding domain (magenta), suggesting a potential role for the SH₂-phosphotyrosine interaction in the stabilization of DNA interacting elements. [Part (b) after X. Chen et al., 1998, *Cell* **93**:827.]

HER1 mutants that lack kinase activity do not undergo accelerated endocytosis in the presence of ligand. It is likely that ligand-induced activation of the kinase activity in normal HER1 induces a conformational change in the cytosolic tail, exposing a sorting motif that facilitates receptor recruitment into clathrin-coated pits and subsequent internalization of the receptor-ligand complex. Despite extensive study of mutant HER1 cytosolic domains, the identity of these “sorting motifs” is controversial, and most likely multiple motifs function to enhance endocytosis. Interestingly, inter-

nalized receptors can continue to signal from endosomes or other intracellular compartments before their degradation, as evidenced by their binding to signaling proteins such as Grb-2 and Sos, which are discussed in the next section.

Lysosomal Degradation After internalization, some cell-surface receptors (e.g., the LDL receptor) are efficiently recycled to the surface (see Figure 14-29). As noted above, the fraction of activated HER1 receptors that are sorted to lysosomes can vary from 20 to 80 percent in different cell types.

There are several potential processes that can influence the recycling versus lysosomal degradation fates of surface receptors. One is covalent modification by the small protein ubiquitin (see Chapter 3). There is a strong correlation between monoubiquitination (addition of a single ubiquitin to a given lysine of a protein) of the HER1 cytosolic domain and HER1 degradation. The monoubiquitination is mediated by the enzyme c-Cbl. An E3 ubiquitin ligase (see Figure 3-29), c-Cbl contains an EGFR-binding domain, which binds directly to phosphorylated EGF receptors, and a RING finger domain, which recruits ubiquitin-conjugating enzymes and mediates transfer of ubiquitin to the receptor. The ubiquitin functions as a “tag” on the receptor that stimulates its incorporation from endosomes into multivesicular bodies (see Figure 14-33) that ultimately are degraded inside lysosomes. A role for c-Cbl in EGF receptor trafficking emerged from genetic studies in *C. elegans*, which established that c-Cbl negatively regulates the function of the nematode EGF receptor (Let-23), probably by inducing its degradation. Similarly, knockout mice lacking c-Cbl show hyperproliferation of mammary gland epithelia, consistent with a role of c-Cbl as a negative regulator of EGF signaling.

Experiments with mutant cell lines demonstrate that internalization of RTKs plays an important role in regulating cellular responses to EGF and other growth factors. For instance, a mutation in the EGF receptor (HER1) that prevents it from being incorporated into coated pits makes it resistant to receptor-mediated (ligand-induced) endocytosis. As a result, this mutation leads to substantially above-normal numbers of EGF receptors on cells and thus increased sensitivity of cells to EGF as a mitogenic signal. Such mutant cells are prone to EGF-induced transformation into tumor cells (see Chapter 24). Interestingly, the other EGF family receptors—HER2, HER3, and HER4—do not undergo ligand-induced internalization, an observation that emphasizes how each receptor evolved to be regulated in its own appropriate manner.

Phosphotyrosine Phosphatases These dephosphorylating enzymes specifically hydrolyze phosphotyrosine linkages on specific target proteins. An excellent example of how phosphotyrosine phosphatase enzymes function to suppress the activity of protein tyrosine kinases is provided by SHP1, the phosphatase that negatively regulates signaling from several types of cytokine receptors. Its role was first identified from analysis of mice lacking this protein; they died because of excess production of erythrocytes and several other types of blood cells.

SHP1 dampens cytokine signaling by binding to a cytokine receptor and inactivating the associated JAK protein, as is depicted in Figure 16-14a. In addition to a phosphatase catalytic domain, SHP1 has two SH2 domains. When cells are in the resting state, unstimulated by a cytokine, one of the SH2 domains in SHP1 physically binds to and inactivates the catalytic site in the phosphatase domain. In the stimulated state, however, this blocking SH2 domain binds to a specific phosphotyrosine residue in the activated receptor. The conformational change that accompanies this binding

(a) Short-term regulation: JAK2 deactivation by SHP1 phosphatase

(b) Long-term regulation: signal blocking and protein degradation by SOCS proteins

FIGURE 16-14 Two mechanisms for terminating signal transduction from the erythropoietin receptor (EpoR). (a) Short-term regulation: SHP1, a phosphotyrosine phosphatase, is present in an inactive form in unstimulated cells. Binding of an SH2 domain in SHP1 to a particular phosphotyrosine in the activated receptor unmasks its phosphatase catalytic site and positions it near the phosphorylated tyrosine in the lip region of JAK2. Removal of the phosphate from this tyrosine inactivates the JAK kinase. (b) Long-term regulation: SOCS proteins, whose expression is induced by STAT proteins in erythropoietin-stimulated erythroid cells, inhibit or permanently terminate signaling over longer time periods. Binding of SOCS to phosphotyrosine residues on EpoR or JAK2 blocks binding of other signaling proteins (left). The SOCS box can also target proteins such as JAK2 for degradation by the ubiquitin-proteasome pathway (right). Similar mechanisms regulate signaling from other cytokine receptors. [Part (a) adapted from S. Constantinescu et al., 1999, *Trends Endocrin. Metabol.* 10:18; part (b) adapted from B. T. Kile and W. S. Alexander, 2001, *Cell. Mol. Life Sci.* 58:1.]

unmasks the SHP1 catalytic site and also brings it adjacent to the phosphotyrosine residue in the activation lip of the JAK associated with the receptor. By removing this phosphate, SHP1 inactivates the JAK, so that it can no longer phosphorylate the receptor or other substrates (e.g. STATs) unless additional cytokine molecules bind to cell-surface receptors, initiating a new round of signaling.

SOCS Proteins In a classic example of negative feedback, among the genes whose transcription is induced by STAT proteins are those encoding a class of small proteins termed *SOCS proteins*, which terminate signaling from cytokine receptors. These negative regulators act in two ways (Figure 16-14b). First, the SH2 domain in several SOCS proteins binds to phosphotyrosines on an activated receptor, preventing binding of other SH2-containing signaling proteins (e.g., STATs) and thus competitively inhibiting receptor signaling. One SOCS protein, SOCS-1, also binds to the critical phosphotyrosine in the activation lip of activated JAK2 kinase, thereby inhibiting its catalytic activity. Second, all SOCS proteins contain a domain, called the SOCS box, that recruits components of E3 ubiquitin ligases (see Figure 3-29). As a result of binding SOCS-1, for instance, JAK2 becomes polyubiquitinated (a polymer of ubiquitins covalently attached to the side chain of a lysine) and is then degraded in **proteasomes**, thereby permanently turning off all JAK2-mediated signaling pathways until new JAK2 proteins can be made. The observation that proteasome inhibitors prolong JAK2 signal transduction supports this mechanism.

Studies with cultured mammalian cells have shown that the receptor for growth hormone, which belongs to the cytokine receptor superfamily, is down-regulated by another SOCS protein, SOCS-2. Strikingly, mice deficient in SOCS-2 grow significantly larger than their wild-type counterparts and have long bone lengths and proportionate enlargement of most organs. Thus SOCS proteins play an essential negative role in regulating intracellular signaling from the receptors for erythropoietin, growth hormone, and other cytokines.

KEY CONCEPTS of Section 16.1

Receptors That Activate Protein Tyrosine Kinases

- Two broad classes of receptors activate tyrosine kinases: (1) receptor tyrosine kinases (RTKs), in which the kinase is an intrinsic part of the receptor, and (2) cytokine receptors, in which the kinase is bound tightly to the cytosolic domain of the receptor. Signaling from receptor tyrosine kinases and cytokine receptors activate similar downstream signaling pathways (see Figure 16-2).
- Receptor tyrosine kinases, which bind to peptides and signaling proteins such as growth factors and insulin, may exist as preformed dimers or dimerize during binding to ligands. Ligand binding triggers formation of functional dimeric receptors, a necessary step in activation of the receptor-associated kinase.

- Activation of an RTK leads to phosphorylation of the activation lip in the protein tyrosine kinases that are an intrinsic part of their cytoplasmic domains, enhancing their catalytic activity (see Figure 16-3). The activated kinase then phosphorylates tyrosine residues in the receptor cytosolic domain and in other protein substrates.

- Humans express many RTKs, four of which (HER1-4) define the epidermal growth factor receptor family that mediates signaling from different members of the epidermal growth factor family of signaling molecules (see Figure 16-7). One of these receptors, HER2, does not bind ligand; it forms active heterodimers with ligand-bound monomers of the other three HER proteins. Overexpression of HER2 is implicated in about 25 percent of breast cancers.

- Cytokines play numerous roles in development. Erythropoietin, a cytokine secreted by kidney cells, promotes proliferation and differentiation of erythroid progenitor cells in the bone marrow (see Figure 16-8) to increase the number of mature red cells in the blood.

- All cytokine receptors have similar structures, and their cytosolic domains are tightly bound to a JAK protein tyrosine kinase, which becomes activated after cytokine binding and receptor dimerization (see Figure 16-10).

- In both RTKs and cytokine receptors, short amino acid sequences containing a phosphotyrosine residue are bound by proteins with conserved SH2 or PTB domains, which are found in many signal-transducing proteins. The sequence of amino acids surrounding the phosphorylated tyrosine determines which domain will bind to it. Such protein-protein interactions are important in many signaling pathways (see Figures 16-11 and 16-12).

- The *JAK/STAT pathway* operates downstream from all cytokine receptors and some RTKs. STAT monomers bound to phosphotyrosines on receptors are phosphorylated by receptor-associated JAKs, then dimerize and move to the nucleus, where they activate transcription (see Figure 16-13).

- Endocytosis of receptor-hormone complexes and their degradation in lysosomes is a principal way of reducing the number of receptor tyrosine kinases and cytokine receptors on the cell surface, thus decreasing the sensitivity of cells to many peptide hormones.

- Signaling from cytokine receptors is terminated by the phosphotyrosine phosphatase SHP1 and several SOCS proteins (see Figure 16-14).

16.2 The Ras/MAP Kinase Pathway

Almost all receptor tyrosine kinases and cytokine receptors activate the *Ras/MAP kinase pathway* (see Figure 16-2b). The **Ras protein**, a monomeric (small) G protein, belongs to the **GTPase superfamily** of intracellular switch proteins (see Figure 15-7). Activated Ras promotes formation, at the

membrane, of signal transduction complexes containing three sequentially acting protein kinases. This *kinase cascade* culminates in activation of certain members of the MAP kinase family, which can translocate into the nucleus and phosphorylate many different proteins. Among the target proteins for MAP kinase are transcription factors that regulate expression of proteins with important roles in the cell cycle and in differentiation. Importantly, different types of extracellular signals often activate different signaling pathways that result in activation of different members of the MAP kinase family.

Because an activating mutation in a RTK, Ras, or a protein in the MAP kinase cascade is found in almost all types of human tumors, the RTK/Ras/MAP kinase pathway has been subjected to extensive study and a great deal is known about the components of this pathway. We begin our discussion by reviewing how Ras cycles between the active and inactive state. We then describe how Ras is activated and passes a signal to the MAP kinase pathway. Finally we examine recent studies indicating that both yeasts and cells of higher eukaryotes contain multiple MAP kinase pathways and consider the ways cells keep different MAP kinase pathways separate from one another through the use of scaffold proteins.

Ras, a GTPase Switch Protein, Operates Downstream of Most RTKs and Cytokine Receptors

Like the G_α subunits in trimeric G proteins discussed in Chapter 15, the monomeric G protein known as Ras alternates between an active “on” state with a bound GTP and an inactive “off” state with a bound GDP (see Figure 15-6 to review this concept). Unlike trimeric G proteins, Ras is not directly linked to cell-surface receptors. Ras (~170 amino acids) is smaller than G_α proteins (~300 amino acids), but the GTP-binding domains of the two proteins have a similar structure (see Figure 15-7 to review the structure of Ras). Structural and biochemical studies show that G_α also contains a GTPase-activating protein (GAP) domain that increases the intrinsic rate of GTP hydrolysis by G_α . Because this domain is not present in Ras, it has an intrinsically slower rate of GTP hydrolysis. Thus the average lifetime of a GTP bound to Ras is about 1 minute, which is much longer than the average lifetime of a G_α ·GTP complex.

The activity of the Ras protein is regulated by several factors. Ras activation is accelerated by a *guanine nucleotide exchange factor* (GEF), which binds to the Ras·GDP complex, causing dissociation of the bound GDP (see Figure 15-6). Because GTP is present in cells at a higher concentration than GDP, GTP binds spontaneously to “empty” Ras molecules, with release of GEF and formation of the active Ras·GTP. Subsequent hydrolysis of the bound GTP to GDP deactivates Ras. Because the intrinsic GTPase activity of Ras·GTP is low compared to that of G_α ·GTP, Ras·GTP requires the assistance of another protein, a GTPase-activating protein (GAP), to deactivate it. Binding of GAP to Ras·GTP accelerates the intrinsic GTPase activity of Ras by more than

a hundredfold; the actual hydrolysis of GTP is catalyzed by amino acids from both Ras and GAP. In particular, insertion of one of GAP’s arginine side chains into the Ras active site stabilizes an intermediate in the hydrolysis reaction.

Mammalian Ras proteins have been studied in great detail because mutant Ras proteins are associated with many types of human cancer. These mutant proteins, which bind but cannot hydrolyze GTP, are permanently in the “on” state and contribute to oncogenic transformation (see Chapter 24). Determination of the three-dimensional structure of the Ras-GAP complex and tests of mutant forms of Ras explained the puzzling observation that most oncogenic, constitutively active Ras proteins (Ras^D) contain a mutation at position 12. Replacement of the normal glycine-12 with any other amino acid (except proline) blocks the functional binding of GAP and in essence “locks” Ras in the active GTP-bound state. ■

The first indication that Ras functions downstream from RTKs in a common signaling pathway came from experiments in which cultured fibroblast cells were induced to proliferate by treatment with a mixture of two protein hormones: platelet-derived growth factor (PDGF) and epidermal growth factor (EGF). Microinjection of anti-Ras antibodies into these cells blocked cell proliferation. Conversely, injection of Ras^D, a constitutively active mutant Ras protein that hydrolyzes GTP very inefficiently and thus persists in the active state, caused the cells to proliferate in the absence of the growth factors. These findings are consistent with studies, using the pull-down assay method detailed in Figure 15-14, showing that addition of FGF to fibroblasts leads to a rapid increase in the proportion of Ras present in the GTP-bound active form. However, as we will see, an activated RTK (or cytokine receptor) cannot directly activate Ras. Instead, other proteins must first be recruited to the activated receptor and serve as adaptors.

Genetic Studies in *Drosophila* Identified Key Signal-Transducing Proteins in the Ras/MAP Kinase Pathway

Our knowledge of the proteins involved in the Ras/MAP kinase pathway came principally from genetic analyses of mutant fruit flies (*Drosophila*) and worms (*C. elegans*) that were blocked at particular stages of differentiation. To illustrate the power of this experimental approach, we consider development of a particular type of cell in the compound eye of *Drosophila*.

The compound eye of the fly is composed of some 800 individual eyes called *ommatidia* (Figure 16-15a). Each ommatidium consists of 22 cells, eight of which are photosensitive neurons called *retinula*, or R cells, designated R1–R8 (Figure 16-15b). An RTK called *Sevenless* (*Sev*) specifically regulates development of the R7 cell and is not essential for any other known function. In flies with a mutant *sevenless* (*sev*) gene, the R7 cell in each ommatidium does not form (Figure 16-15c,

FIGURE 16-15 The compound eye of *Drosophila melanogaster*. (a) Scanning electron micrograph showing individual ommatidia that compose the fruit fly eye. (b) Longitudinal and cutaway views of a single ommatidium. Each of these tubular structures contains eight photoreceptors, designated R1–R8, which are long, cylindrically shaped light-sensitive cells. R1–R6 (yellow) extend throughout the depth of the retina, whereas R7 (brown) is located toward the surface of the eye and R8 (blue) toward the back side, where the axons exit. (c) Comparison of eyes from wild-type and *sevenless* mutant flies viewed by a special

technique that can distinguish the photoreceptors in an ommatidium. The plane of sectioning is indicated by the blue arrows in (b), and the R8 cell is out of the plane of these images. The seven photoreceptors in this plane are easily seen in the wild-type ommatidia (top), whereas only six are visible in the mutant ommatidia (bottom). Flies with the *sevenless* mutation lack the R7 cell in their eyes. (Part (a) from E. Hafen and K. Basler, 1991, *Development* 1(suppl.):123; part (b) adapted from R. Reinke and S. L. Zipursky, 1988, *Cell* 55:321; part (c) courtesy of U. Banerjee.]

bottom). Since the R7 photoreceptor is necessary only for flies to see in ultraviolet light, mutants that lack functional R7 cells but are otherwise normal are easily isolated. Therefore, fly R7 cells are an ideal genetic system for studying cell development.

During development of each ommatidium, a protein called *Boss* (*Bride of Sevenless*) is expressed on the surface of the R8 cell. This membrane-tethered protein is the ligand for the Sev RTK on the surface of the neighboring R7 precursor cell, signaling it to develop into a photosensitive neuron (Figure 16-16a). In mutant flies that do not express a functional *Boss* protein or Sev RTK, interaction between the *Boss* and Sev proteins cannot

occur, and no R7 cells develop (Figure 16-16b); this is the origin of the name “Sevenless” for the RTK in the R7 cells.

To identify intracellular signal-transducing proteins in the Sev RTK pathway, investigators produced mutant flies expressing a temperature-sensitive Sev protein. When these flies were maintained at a permissive temperature, all their ommatidia contained R7 cells; when they were maintained at a nonpermissive temperature, no R7 cells developed. At a particular intermediate temperature, however, just enough of the Sev RTK was functional to mediate normal R7 development. The investigators reasoned that at this intermediate

EXPERIMENTAL FIGURE 16-16 Genetic studies reveal that activation of Ras induces development of R7 photoreceptors in the *Drosophila* eye. (a) During larval development of wild-type flies, the R8 cell in each developing ommatidium expresses a cell-surface protein, called *Boss*, which binds to the Sev RTK on the surface of its neighboring R7 precursor cell. This interaction induces changes in gene expression that result in differentiation of the precursor cell into a functional R7 neuron. (b) In fly embryos with a mutation in the *sevenless* (*sev*) gene, R7 precursor cells cannot bind *Boss* and therefore do not differentiate normally into R7 cells. Rather, the precursor cell enters an alternative developmental pathway and eventually becomes a cone cell. (c) Double-mutant larvae (*sev*[−]; *Ras*^D) express a constitutively active Ras (*Ras*^D) in the R7 precursor cell, which induces differentiation of R7 precursor cells in the absence of the *Boss*-mediated signal. This finding shows that activated Ras is sufficient to mediate induction of an R7 cell. [See M. A. Simon et al., 1991, *Cell* 67:701, and M. E. Fortini et al., 1992, *Nature* 355:559.]

FIGURE 16-17 Activation of Ras following ligand binding to receptor tyrosine kinases (RTKs) or cytokine receptors. The receptors for epidermal growth factor (EGF) and many other growth factors are RTKs. The cytosolic adapter protein GRB2 binds to a specific phosphotyrosine on an activated, ligand-bound receptor and to the cytosolic Sos protein, bringing it near the plasma membrane and to its substrate, the inactive Ras-GDP. The guanine nucleotide exchange factor (GEF) activity of Sos then promotes formation of active Ras-GTP. Note that Ras is tethered to the cytosolic surface of the plasma membrane by a hydrophobic farnesyl anchor (see Figure 10-19). [See J. Schlessinger, 2000, *Cell* **103**:211, and M. A. Simon, 2000, *Cell* **103**:13.]

temperature, the signaling pathway would become defective (and thus no R7 cells would develop) if the level of another protein involved in the pathway was reduced, thereby reducing the activity of the overall pathway below the level required to form an R7 cell. A recessive mutation affecting such a protein would have this effect because, in diploid organisms such as *Drosophila*, a heterozygote containing one wild-type and one mutant allele of a gene will produce half the normal amount of the gene product; hence, even if such a recessive mutation is in an essential gene, the organism will usually be viable. However, a fly carrying a temperature-sensitive mutation in the *sev* gene and a second mutation affecting another protein in the signaling pathway would be expected to lack R7 cells at the intermediate temperature.

By use of this screen, researchers identified three genes encoding important proteins in the *Sev* pathway: an SH2-containing adapter protein exhibiting 64 percent amino acid sequence identity to human GRB2 (growth factor receptor-bound protein 2), a guanine nucleotide exchange factor called Sos (Son of Sevenless) exhibiting 45 percent identity with its mouse counterpart, and a Ras protein exhibiting 80 percent identity with its mammalian counterparts. These three proteins later were found to function in other signaling pathways initiated by ligand binding to different RTKs and used at different times and places in the developing fly.

In subsequent studies, researchers introduced a mutant *ras^D* gene into fly embryos carrying the sevenless mutation. As noted earlier, the *ras^D* gene encodes a constitutively active Ras protein that is present in the active GTP-bound form even in the absence of a hormone signal. Although no functional *Sev* RTK was expressed in these double mutants (*sev⁻; ras^D*), R7 cells formed normally, indicating that presence of an activated Ras protein is sufficient for induction of R7-cell development (Figure 16-16c). This finding, which is consistent with the results with cultured fibroblasts described earlier, supports the conclusion that activation of Ras is a principal step in intracellular signaling by most if not all RTKs and cytokine receptors.

Receptor Tyrosine Kinases and JAK Kinases Are Linked to Ras by Adapter Proteins

In order for activated RTKs and cytokine receptors to activate Ras, two cytosolic proteins—GRB2 and Sos—must first be recruited to provide a link between the receptor and Ras (Figure 16-17). GRB2 is an *adapter protein*, meaning that it

has no enzymatic activity and serves as a link, or scaffold, between two other proteins—in this case between the activated receptor and Sos. Sos is a guanine nucleotide exchange protein (GEF), which catalyzes conversion of inactive GDP-bound Ras to the active GTP-bound form.

GRB2 is able to serve as an adapter protein because of its SH2 domain, which binds to a specific phosphotyrosine residue in the activated RTK (or cytokine receptor). In addition to its SH2 domain, the GRB2 adapter protein contains two SH3 domains, which bind to Sos, the Ras guanine nucleotide exchange factor (Figure 16-17). Like phosphotyrosine-binding SH2 and PTB domains, SH3 domains are present in a large number of proteins involved in intracellular signaling. Although the three-dimensional structures of various SH3 domains are similar, their specific amino acid sequences differ. The SH3 domains in GRB2 selectively bind to proline-rich sequences in Sos; different SH3 domains in other proteins bind to proline-rich sequences distinct from those in Sos.

Proline residues play two roles in the interaction between an SH3 domain in an adapter protein (e.g., GRB2) and a proline-rich sequence in another protein (e.g., Sos). First, the proline-rich sequence assumes an extended conformation that permits extensive contacts with the SH3 domain, thereby facilitating interaction. Second, a subset of these prolines fit into binding “pockets” on the surface of the SH3 domain (Figure 16-18). Several nonproline residues also interact with the SH3 domain and are responsible for determining the binding specificity. Hence the binding of proteins to SH3 and

to SH2 domains follows a similar strategy: certain residues provide the key structural motif necessary for binding, and neighboring residues confer specificity to the binding.

Binding of Sos to Inactive Ras Causes a Conformational Change That Triggers an Exchange of GTP for GDP

Following activation of an RTK (e.g., the EGF receptor), a complex containing the activated receptor, GRB2, and Sos is formed on the cytosolic face of the plasma membrane (see Figure 16-17). Complex formation depends on the ability of GRB2 to bind *simultaneously* to the receptor and to Sos. Thus receptor activation leads to relocation of Sos from the cytosol to the membrane, bringing Sos near to its substrate, namely, Ras•GDP that is already bound to the plasma membrane by means of a covalently attached lipid. Binding of Sos to Ras•GDP leads to conformational changes in the Switch I and Switch II segments of Ras, thereby opening the binding pocket for GDP so it can diffuse out (Figure 16-19). In other words, Sos functions as a GEF for Ras. GTP then binds to and activates Ras. Binding of GTP to Ras, in turn, induces a specific conformation of Switch I and Switch II that allows Ras•GTP to activate the next protein in the Ras/MAP kinase pathway.

Signals Pass from Activated Ras to a Cascade of Protein Kinases, Ending with MAP Kinase

Biochemical and genetic studies in yeast, *C. elegans*, *Drosophila*, and mammals have revealed that downstream of Ras is a highly conserved cascade of three protein kinases, culminating in MAP kinase. Although activation of the kinase cascade does not yield the same biological results in all cells, a common set of sequentially acting kinases defines the Ras/MAP kinase pathway, as outlined in Figure 16-20. Ras is activated by exchange of GDP for GTP (step 1). Active Ras•GTP binds to the N-terminal regulatory domain of Raf, a serine/threonine (not tyrosine) kinase, thereby activating it (step 2). In unstimulated cells, Raf is phosphorylated and bound in an inactive state to the phosphoserine-binding protein 14-3-3. Hydrolysis of Ras•GTP to Ras•GDP releases active Raf from its complex with 14-3-3 (step 3), and Raf subsequently phosphorylates and thereby activates MEK (step 4). (A dual-specificity protein kinase, MEK phosphorylates its target proteins on both tyrosine and serine/threonine residues.) Active MEK then phosphorylates and activates MAP kinase, another serine/threonine kinase also known as ERK (step 5). MAP kinase phosphorylates many different proteins, including nuclear transcription factors that mediate cellular responses (step 5).

Several types of experiments have demonstrated that Raf, MEK, and MAP kinase lie downstream from Ras and have revealed the sequential order of these proteins in the pathway. For example, mutant Raf proteins missing the N-terminal regulatory domain are constitutively active and induce quiescent cultured cells to proliferate in the absence of stimulation

FIGURE 16-18 Surface model of an SH3 domain bound to a target peptide. The short, proline-rich target peptide is shown as a space-filling model. In this target peptide, two prolines (Pro4 and Pro7, dark blue) fit into binding pockets on the surface of the SH3 domain. Interactions involving an arginine (Arg1, red), two other prolines (light blue), and other residues in the target peptide (green) determine the specificity of binding. [After H. Yu et al., 1994, *Cell* 76:933.]

FIGURE 16-19 Structures of Ras bound to GDP, Sos protein, and GTP. (a) In Ras-GDP, the Switch I (green) and Switch II (blue) segments do not directly interact with GDP. (b) One α helix (brown) in Sos binds to both switch regions of Ras-GDP, leading to a massive conformational change in Ras. In effect, Sos pries Ras open by displacing the Switch I region, thereby allowing GDP to diffuse out. (c) GTP is thought to bind to the Ras-Sos complex first through its base (guanine); subsequent

binding of the GTP phosphates completes the interaction. The resulting conformational change in Switch I and Switch II segments of Ras, allowing both to bind to the GTP γ phosphate, displaces Sos and promotes interaction of Ras-GTP with its effectors (discussed later). See Figure 15-8 for another depiction of Ras-GDP and Ras-GTP. [Adapted from P. A. Boriack-Sjodin and J. Kuriyan, 1998, *Nature* **394**:341.]

FIGURE 16-20 Ras/MAP kinase pathway. In unstimulated cells, most Ras is in the Inactive form with bound GDP; binding of a ligand to its RTK or cytokine receptor leads to formation of the active Ras-GTP complex (step 1; see also Figure 16-17). Activated Ras triggers the downstream kinase cascade depicted in steps 2–6, culminating in activation of MAP kinase (MAPK). In unstimulated cells, binding of a dimer of the 14-3-3 protein to Raf stabilizes it in an inactive conformation (the 14-3-3 protein binds phosphoserine residues in a number of important signaling proteins). Each 14-3-3 monomer binds to a phosphoserine residue in Raf, one to phosphoserine-259 in the N-terminal domain and the other to phosphoserine-621 in the kinase domain. Interaction of the Raf N-terminal regulatory domain with Ras-GTP results in dephosphorylation of one of the serines that bind Raf to 14-3-3, phosphorylation of other residues, and activation of Raf kinase activity. After inactive Ras-GDP dissociates from Raf, it presumably can be reactivated by signals from activated receptors, thereby recruiting additional Raf molecules to the membrane. [See E. Kerkhoff and U. Rapp, 2001, *Adv. Enzyme Regul.* **41**:261; J. Avruch et al., 2001, *Recent Prog. Hormone Res.* **56**:127; and M. Yip-Schneider et al., 2000, *Biochem. J.* **351**:151.]

by growth factors. These mutant Raf proteins were initially identified in tumor cells; like the constitutively active Ras^D protein, such mutant Raf proteins are said to be encoded by **oncogenes**, whose encoded proteins promote transformation of the cells in which they are expressed (see Chapter 24). Conversely, cultured mammalian cells that express a mutant, non-functional Raf protein cannot be stimulated to proliferate uncontrollably by a constitutively active Ras^D protein. This finding established a link between the Raf and Ras proteins and that Raf lies downstream of Ras in the signaling pathway. In vitro binding studies further showed that the purified Ras•GTP protein binds directly to the N-terminal regulatory domain of Raf and activates its catalytic activity.

That MAP kinase is activated in response to Ras activation was demonstrated in quiescent cultured cells expressing a constitutively active Ras^D protein. In these cells, activated MAP kinase is generated in the absence of stimulation by growth-promoting hormones. More importantly, R7 photoreceptors develop normally in the developing eye of *Drosophila* mutants that lack a functional Ras or Raf protein but express a constitutively active MAP kinase. This finding indicates that activation of MAP kinase is sufficient to transmit a proliferation or differentiation signal normally initiated by ligand binding to a receptor tyrosine kinase such as Sevenless (see Figure 16-16). Biochemical studies showed, however, that Raf cannot directly phosphorylate MAP kinase or otherwise activate its activity.

The final link in the kinase cascade activated by Ras•GTP emerged from studies in which scientists fractionated extracts of cultured cells searching for a kinase activity that could phosphorylate MAP kinase and that was present only in cells stimulated with growth factors, not unstimulated cells. This work led to identification of MEK, a kinase that specifically phosphorylates one threonine and one tyrosine residue on the activation lip of MAP kinase, thereby activating its catalytic activity. (The acronym *MEK* comes from MAP and ERK kinase.) Later studies showed that MEK binds to the C-terminal catalytic domain of Raf and is phosphorylated by the Raf serine/threonine kinase; this phosphorylation activates the catalytic activity of MEK.

Hence activation of Ras induces a kinase cascade that includes Raf, MEK, and MAP kinase: activated RTK → Ras → Raf → MEK → MAP kinase. Although we will not emphasize this here, the complexity of this pathway is increased by the multiple isoforms of each of its components. In humans, there are three RAS, three Raf, two MEK, and two Erk proteins, and each of these has overlapping but also nonredundant functions.

 Activating mutations in the *B-Raf* gene occur in over 40 percent of melanomas, a skin cancer that is often caused by exposure to ultraviolet radiation in sunlight. Of these melanomas, one particular mutation, a glutamic acid substitution for the valine at position 600, accounts for over 90 percent. This mutant *B-Raf* stimulates MEK-ERK signaling in cells in the absence of growth factors, and mutant *B-Raf* transgenes induce melanoma in mice. Very potent and

selective inhibitors of the *B-Raf* kinase have recently entered the clinic and are producing excellent responses in patients with *B-Raf* mutant melanoma. ■

Phosphorylation of MAP Kinase Results in a Conformational Change That Enhances Its Catalytic Activity and Promotes Kinase Dimerization

Biochemical and x-ray crystallographic studies have provided a detailed picture of how phosphorylation activates MAP kinase. As in JAK kinases and receptor tyrosine kinases, the catalytic site in the inactive, unphosphorylated form of MAP kinase is blocked by a stretch of amino acids, the activation lip (Figure 16-21a). Binding of MEK to MAP kinase destabilizes the lip structure, resulting in exposure of tyrosine-185, which is buried in the inactive conformation. Following phosphorylation of this critical tyrosine, MEK phosphorylates the neighboring threonine-183 (Figure 16-21b).

Both the phosphorylated tyrosine and the phosphorylated threonine residue in MAP kinase interact with additional amino acids, thereby conferring an altered conformation to the lip region, which in turn permits binding of ATP to the

FIGURE 16-21 Structures of inactive, unphosphorylated MAP kinase and the active, phosphorylated form. (a) In inactive MAP kinase, the activation lip is in a conformation such that it blocks the kinase active site. (b) Phosphorylation by MEK at tyrosine-185 (Y185) and threonine-183 (T183) leads to a marked conformational change in the activation lip. This activating change both promotes binding of its substrates—ATP and its target proteins—to the kinase and MAP kinase dimerization. A similar phosphorylation-dependent mechanism activates JAK kinases and the intrinsic kinase activity of RTKs.

[After B. J. Canagarajah et al., 1997, *Cell* 90:859.]

catalytic site, which, as in all kinases, is in the groove between the upper and lower kinase domains. The phosphotyrosine residue (pY185) also plays a key role in binding specific substrate proteins to the surface of MAP kinase. Phosphorylation promotes not only the catalytic activity of MAP kinase but also its dimerization. The dimeric form of MAP kinase is translocated to the nucleus, where it regulates the activity of many nuclear transcription factors.

MAP Kinase Regulates the Activity of Many Transcription Factors Controlling Early Response Genes

Addition of a growth factor (e.g., EGF or PDGF) to quiescent (non-growing) cultured mammalian cells causes a rapid increase in the expression of as many as 100 different genes. These are called *early response genes* because they are induced well before cells enter the S phase and replicate their DNA (see Chapter 20). One important early response gene encodes the transcription factor c-Fos. Together with other transcription factors, such as c-Jun, c-Fos induces expression

of many genes encoding proteins necessary for cells to progress through the cell cycle. Most RTKs that bind growth factors utilize the MAP kinase pathway to activate genes encoding proteins such as c-Fos, which in turn propel the cell through the cell cycle.

The enhancer that regulates the *c-fos* gene contains a *serum response element* (SRE), so named because it is activated by many growth factors in serum. This complex enhancer contains DNA sequences that bind multiple transcription factors. As depicted in Figure 16-22, activated (phosphorylated) dimeric MAP kinase induces transcription of the *c-fos* gene by direct activation of one transcription factor, *ternary complex factor* (TCF), and indirect activation of another, *serum response factor* (SRF). In the cytosol, MAP kinase phosphorylates and activates a kinase called p90^{RSK}, which translocates to the nucleus, where it phosphorylates a specific serine in SRF. After translocating to the nucleus, MAP kinase directly phosphorylates specific serines in TCF. Association of phosphorylated TCF with two molecules of phosphorylated SRF forms an active trimeric factor that activates gene transcription.

FIGURE 16-22 Induction of gene transcription by MAP kinase. Steps **1–3**: In the cytosol, MAP kinase phosphorylates and activates the kinase p90^{RSK}, which then moves into the nucleus and phosphorylates the SRF transcription factor. Steps **4** and **5**: After translocating into the nucleus, MAP kinase directly phosphorylates the transcription

factor TCF that is already bound to the promoter of the *c-fos* gene. Step **6**: Phosphorylated TCF and SRF act together to stimulate transcription of genes (e.g., *c-fos*) that contain an SRE sequence in their promoter. See the text for details. [See R. Marais et al., 1993, *Cell* **73**:381, and V. M. Rivera et al., 1993, *Mol. Cell Biol.* **13**:6260.]

FIGURE 16-23 Pheromone-induced mating of haploid yeast cells. The α cells produce α mating factor and a -factor receptor; the a cells produce a factor and α -factor receptor. Both receptors are G protein-coupled receptors. Binding of the mating factors to their cognate receptors on cells of the opposite type leads to gene activation, resulting in mating and production of diploid cells. In the presence of sufficient nutrients, these cells will grow as diploids. Without sufficient nutrients, the cells will undergo meiosis and form four haploid spores.

G Protein-Coupled Receptors Transmit Signals to MAP Kinase in Yeast Mating Pathways

Although in multicellular animals MAP kinase is often activated by RTKs or cytokine receptors, signaling from other receptors can activate MAP kinase in different eukaryotic cells (see Figure 15-34). To illustrate, we consider the mating pathway in *S. cerevisiae*, a well-studied example of a MAP kinase cascade linked to G protein-coupled receptors (GPCRs), in this case for two secreted peptide pheromones, the a and α factors.

Haploid yeast cells are either of the a or α mating type and secrete protein signals known as pheromones, which induce mating between haploid yeast cells of the opposite mating type, a or α . An a haploid cell secretes the a mating factor and has cell-surface receptors for the α factor; an α cell secretes the α factor and has cell-surface receptors for the a factor (see Figure 16-23). Thus each type of cell recognizes the mating factor produced by the opposite type. Activation of the MAP kinase pathway by either the a or α receptors induces transcription of genes that inhibit progression of the cell cycle and others that enable cells of opposite mating type to fuse together and ultimately form a diploid cell.

Ligand binding to either of the two yeast pheromone GPCRs triggers the exchange of GTP for GDP on the G_α subunit and dissociation of G_α -GTP from the $G_{\beta\gamma}$ complex. This activation process is identical to that for the GPCRs discussed in the previous chapter (see Figure 15-17). In many mammalian GPCR-initiated pathways, the active G_α transduces the signal. In contrast, mutant and biochemical studies have shown that the dissociated $G_{\beta\gamma}$ complex mediates all the physiological responses induced by activation of the yeast pheromone receptors (Figure 16-24a). For instance, in yeast cells that lack G_α , the $G_{\beta\gamma}$ subunit is always free. Such cells can mate in the absence of mating factors; that is, the mating response is constitutively on. However, in cells defective for the G_β or G_γ subunit, the mating pathway cannot be induced at all. If dissociated G_α were the transducer, in these mutant cells the pathway would be expected to be constitutively active.

In yeast mating pathways, $G_{\beta\gamma}$ functions by triggering a kinase cascade that is analogous to the one downstream from Ras; each protein has a yeast-specific name but shares sequences with and is analogous in structure and function to the corresponding mammalian protein shown in Figure 16-20. The components of this cascade were uncovered mainly through analyses of mutants that possess functional a and α receptors and G proteins but are sterile (*Ste*), or defective in mating responses. The physical interactions between the components were assessed through immunoprecipitation experiments with extracts of yeast cells and other types of studies. Based on these studies, scientists have proposed the kinase cascade shown in Figure 16-24a. Free $G_{\beta\gamma}$, which is tethered to the membrane via the lipid bound to the γ subunit, binds the Ste5 protein, thus recruiting it and its bound kinases to the plasma membrane. Ste5 has no obvious catalytic function and acts as a scaffold for assembling other components in the cascade (Ste11, Ste7, and Fus3). $G_{\beta\gamma}$ also

FIGURE 16-24 Yeast MAP kinase cascades in the mating and osmoregulatory pathways. In yeast, different receptors activate different MAP kinase pathways, two of which are outlined here. The two MEKs depicted, like all MEKs, are dual specificity threonine/tyrosine kinases; all of the others are serine/threonine kinases. (a) *Mating pathway:* The receptors for yeast α and β mating factors are coupled to the same trimeric G protein. Following ligand binding and dissociation of the G protein subunits, the membrane-tethered $G_{\beta\gamma}$ subunit binds the Ste5 scaffold to the plasma membrane. $G_{\beta\gamma}$ also activates Cdc24, a GEF for the Ras-like protein Cdc42; the active GTP-bound Cdc42 in turn binds to and activates the resident Ste20 kinase. Ste20 then phosphorylates and activates Ste11, which is analogous to Raf and other mammalian MEK kinase (MEKK) proteins. Ste20 thus serves as a MAPKKK kinase. Ste11 initiates a kinase cascade in which the final component, Fus3, is functionally equivalent to MAP kinase (MAPK) in higher eukaryotes. Like other MAP kinases, activated Fus3 then translocates into the nucleus. There it phosphorylates two proteins, Dig1 and Dig2, relieving their inhibition of the Ste12 transcription

factor, allowing it to bind to DNA and initiate transcription of genes that inhibit progression of the cell cycle and others that enable cells of opposite mating type to fuse together and ultimately form a diploid cell. (b) *Osmoregulatory pathway:* Two plasma membrane proteins, Sho1 and Msb1, are activated in an unknown manner by exposure of yeast cells to media of high osmotic strength. Activated Sho1 recruits the Pbs2 scaffold protein, which contains a MEK domain, to the plasma membrane. Similar to the mating pathway, at the plasma membrane the Sho1 Msb1 complex also activates Cdc42, which in turn activates the resident Ste20 kinase. Ste20 in turn phosphorylates and activates Ste11, initiating a kinase cascade that activates Hog1, a MAP kinase. In the cytosol, Hog1 phosphorylates specific protein targets, including ion channels; after translocating to the nucleus, Hog1 phosphorylates several transcription factors and chromatin-modifying enzymes. Hog1 appears also to promote transcriptional elongation. Together, the newly synthesized and modified proteins support survival in high-osmotic-strength media. [After N. Dard and M. Peter, 2006, *BioEssays* **28**:146, and R. Chen and J. Thorner, 2007, *Biochim. Biophys. Acta* **1773**:1311.]

activates *cdc24*, a GEF for the Ras-like protein *cdc 42*; GTP-*cdc42* in turn activates the Ste20 protein kinase. Ste20 phosphorylates and activates Ste11, a serine/threonine kinase analogous to Raf and other mammalian MEKK proteins. Activated Ste11 then phosphorylates Ste7, a dual-specificity MEK that then phosphorylates and activates Fus3, a serine/threonine kinase equivalent to MAP kinase. After translocation to the nucleus, Fus3 phosphorylates two proteins, Dig1 and Dig2, relieving their inhibition of the Ste12 transcription factor. Activated Ste12 in turn induces expression of proteins involved in mating-specific cellular responses. Fus3 also affects gene expression through phosphorylating other proteins.

Scaffold Proteins Separate Multiple MAP Kinase Pathways in Eukaryotic Cells

Thus both yeasts and higher eukaryotic cells contain a Ras/MAP kinase signaling pathway that is activated by extracellular protein signals and culminates in the MAP kinase-mediated phosphorylation of transcription factors and other signaling proteins that together trigger specific changes in cell behavior. Importantly, all eukaryotes possess multiple highly conserved MAP kinase pathways that are activated by different extracellular signals and that activate different MAP kinase proteins that phosphorylate different transcription factors; these in turn trigger different changes in cell division, differentiation, or function. Mammalian MAP kinases include *Jun N-terminal kinases* (JNKs) and *p38 kinases*, which become activated by signaling pathways in response to various types of stresses and which phosphorylate different transcription factors and other types of signaling proteins that affect cell division.

Current genetic and biochemical studies in the mouse and *Drosophila* are aimed at determining which MAP kinases mediate which responses to which signals in higher eukaryotes. This has already been accomplished in large part for the simpler organism *S. cerevisiae*. Each of the six MAP kinases encoded in the *S. cerevisiae* genome has been assigned by genetic analyses to specific signaling pathways triggered by various extracellular signals, such as pheromones, high osmolarity, starvation, hypotonic shock, and carbon/nitrogen deprivation. A second yeast MAP kinase cascade, known as the osmoregulatory pathway, is shown in Figure 16-24b. Each yeast MAP kinase mediates very specific cellular responses, as exemplified by Fus3 in the mating pathway and Hog1 in the osmoregulatory pathway.

A complication arises because in both yeasts and higher eukaryotic cells, different MAP kinase cascades share some common components. For instance, the MEKK Ste11 functions in three yeast signaling pathways: the mating pathway, the osmoregulatory pathway, and the filamentous growth pathway, which is induced by starvation. Nevertheless, each pathway activates a distinct MAP kinase. Similarly, in mammalian cells, common upstream signal-transducing proteins participate in activating multiple JNK kinases.

Once the sharing of components among different MAP kinase pathways was recognized, researchers wondered how the specificity of the cellular responses to particular signals is achieved. Studies with yeast provided the initial evidence that pathway-specific *scaffold proteins* enable the signal-transducing kinases in a particular pathway to interact with one another but not with kinases in other pathways. For example, the scaffold protein Ste5 stabilizes a large complex that includes the kinases in the mating pathway; similarly, the Pbs2 scaffold is used for the kinase cascade in the osmoregulatory pathway (see Figure 16-24). In each pathway in which Ste11 participates, it is constrained within a large complex that forms in response to a specific extracellular signal, and signaling downstream from Ste11 is restricted to the complex in which it is localized. As a result, exposure of yeast cells to mating factors induces activation of a single MAP kinase, Fus3, whereas exposure to a high osmolarity induces activation of a different MAP kinase, Hog1.

Scaffolds for MAP kinase pathways are well documented in yeast, fly, and worm cells, but their presence in mammalian cells has been difficult to demonstrate. Perhaps the best-documented scaffold protein in metazoans is *Ksr* (kinase suppressor of Ras), which binds both MEK and MAP kinase. In *Drosophila*, loss of the *Ksr* homolog blocks signaling by a constitutively active Ras protein, suggesting a positive role for *Ksr* in the Ras/MAP kinase pathway in fly cells. Although knockout mice that lack *Ksr* are phenotypically normal, activation of MAP kinase by growth factors or cytokines is lower than normal in several types of cells in these animals. This finding suggests that *Ksr* functions as a scaffold that enhances but is not essential for Ras/MAP kinase signaling in mammalian cells. Thus the signal specificity of different MAP kinases in animal cells may arise from their association with various scaffold-like proteins, but much additional research is needed to test this possibility.

KEY CONCEPTS of Section 16.2

The Ras/MAP Kinase Pathway

- Ras is an intracellular GTPase switch protein that acts downstream from most RTKs and cytokine receptors. Like G_{α} , Ras cycles between an inactive GDP-bound form and an active GTP-bound form. Ras cycling requires the assistance of two proteins: a guanine nucleotide exchange factor (GEF) and a GTPase-activating protein (GAP).
- RTKs are linked indirectly to Ras via two proteins: GRB2, an adapter protein, and Sos, which has GEF activity (see Figure 16-17).
- The SH2 domain in GRB2 binds to a phosphotyrosine in activated RTKs, while its two SH3 domains bind Sos, thereby bringing Sos close to membrane-bound Ras-GDP and activating its nucleotide-exchange activity.

- Binding of Sos to inactive Ras causes a large conformational change that permits release of GDP and binding of GTP, forming active Ras (see Figure 16-19).
- Activated Ras triggers a kinase cascade in which Raf, MEK, and MAP kinase are sequentially phosphorylated and thus activated. Activated MAP kinase then translocates to the nucleus (see Figure 16-20).
- Activation of MAP kinase following stimulation of a growth-factor receptor leads to phosphorylation and activation of two transcription factors, which associate into a trimeric complex that promotes transcription of various early response genes (see Figure 16-22).
- Different extracellular signals induce activation of different MAP kinase pathways, which regulate diverse cellular processes by phosphorylating different sets of transcription factors.
- The kinase components of each MAP kinase cascade assemble into a large pathway-specific complex stabilized by a scaffold protein (see Figure 16-24). This ensures that activation of one MAP kinase pathway by a particular extracellular signal does not lead to activation of other pathways containing shared components.

16.3 Phosphoinositide Signaling Pathways

In previous sections, we have seen how signal transduction from receptor tyrosine kinases (RTKs) and cytokine receptors begins with formation of multiprotein complexes associated with the plasma membrane (see Figures 16-12 and 16-13) and how these complexes initiate the Ras/MAP kinase pathway. Here we discuss how these same receptors initiate signaling pathways that involve as intermediates special phosphorylated phospholipids derived from phosphatidyl inositol. As discussed in Chapter 15, these membrane-bound lipids are collectively referred to as **phosphoinositides**. These phosphoinositide signaling pathways include several enzymes that synthesize different phosphoinositides and proteins with domains that can bind to these molecules and are thus recruited to the cytosolic surface of the plasma membrane. In addition to the short-term effects on cell metabolism we encountered in Chapter 15, these phosphoinositide pathways have long-term effects on the pattern of gene expression. We will see that phosphoinositide pathways end with a variety of kinases, including protein kinase C (PKC) and protein kinase B (PKB), that play key roles in cell growth and metabolism. As an example, later in the chapter we see how insulin activation of PKB plays a key role in stimulating glucose import into muscle.

Phospholipase C_γ Is Activated by Some RTKs and Cytokine Receptors

As discussed in Chapter 15, hormonal stimulation of some G protein-coupled receptors leads to activation of phospholipase C (PLC). This membrane-associated enzyme then cleaves

phosphatidylinositol 4,5-bisphosphate (PIP₂) to generate two important second messengers: 1,2-diacylglycerol (DAG) and inositol 1,4,5-trisphosphate (IP₃). Signaling via the *IP₃/DAG pathway* leads to an increase in cytosolic Ca²⁺ and to activation of protein kinase C (see Figure 15-36).

Although we did not mention it during our discussion of phospholipase C in Chapter 15, it is specifically the β isoform of this enzyme (PLC_β) that is activated by GPCRs. Many RTKs and cytokine receptors also can initiate the IP₃/DAG pathway by activating another isoform of phospholipase C, the γ isoform (PLC_γ), an isoform that contains SH2 domains. The SH2 domains of PLC_γ bind to specific phosphotyrosines on the activated receptors, thus positioning the enzyme close to its membrane-bound substrate, phosphatidyl inositol 4,5-bisphosphate (PIP₂). In addition, the kinase activity associated with receptor activation phosphorylates tyrosine residues on the bound PLC_γ, enhancing its hydrolase activity. Thus activated RTKs and cytokine receptors promote PLC_γ activity in two ways: by localizing the enzyme to the membrane and by phosphorylating it. As seen in Chapter 15, the IP₃/DAG pathway initiated by PLC has multiple physiological effects.

Recruitment of PI-3 Kinase to Activated Receptors Leads to Synthesis of Three Phosphorylated Phosphatidylinositols

Besides the IP₃/DAG pathway, many activated RTKs and cytokine receptors initiate another phosphoinositide pathway by recruiting the enzyme *phosphatidylinositol-3 (PI-3) kinase* to the membrane. PI-3 kinase is recruited to the plasma membrane by binding of its SH2 domain to phosphotyrosines on the cytosolic domain of many activated RTKs and cytokine receptors. This recruitment positions the catalytic domain of PI-3 kinase near its phosphoinositide substrates on the cytosolic face of the plasma membrane. Unlike kinases we have encountered earlier that phosphorylate proteins, PI-3 kinase adds a phosphate to the 3' carbon in the lipid phosphatidylinositol, leading to formation of two separate phosphatidyl inositol 3-phosphates: PI 3,4-bisphosphate or PI 3,4,5-trisphosphate (Figure 16-25). By acting as docking sites for various signal-transducing proteins, these membrane-bound PI 3-phosphate products of the PI-3 kinase reactions in turn transduce signals downstream in several important pathways.

In some cells, this *PI-3 kinase pathway* can trigger cell division and prevent programmed cell death (apoptosis), thus ensuring cell survival. In other cells, this pathway induces specific changes in cell metabolism.

PI-3 kinase was first identified in studies of the polyoma virus, a DNA virus that transforms certain mammalian cells to uncontrolled growth. Transformation requires several viral-encoded oncoproteins, including one termed “middle T.” In an attempt to discover how middle T functions, investigators uncovered PI-3 kinase protein in partially purified preparations of middle T, suggesting a specific interaction between the two. Then they set out to determine how PI-3 kinase might affect cell behavior.

FIGURE 16-25 Generation of phosphatidylinositol 3-phosphates.

The enzyme phosphatidylinositol-3 kinase (PI-3 kinase) is recruited to the membrane by many activated receptor tyrosine kinases (RTKs) and cytokine receptors. The 3-phosphate added by this enzyme, to yield PI 3,4-bisphosphate or PI 3,4,5-trisphosphate, is a binding site for various signal-transduction proteins, such as the PH domain of protein kinase B. PI 4,5-bisphosphate also is the substrate of phospholipase C (see Figure 15-35). [See L. Rameh and L. C. Cantley, 1999, *J. Biol. Chem.* 274:8347.]

When an inactive, dominant-negative version of PI-3 kinase was expressed in polyoma virus-transformed cells, it inhibited the uncontrolled cell proliferation characteristic of virus-transformed cells. This finding suggested that the normal kinase is important in certain signaling pathways essential for cell proliferation or for the prevention of apoptosis. Subsequent work showed that PI-3 kinases participate in many signaling pathways related to cell growth and apoptosis. Of the nine PI-3 kinase homologs encoded by the human genome, the best characterized contains a p110 subunit with catalytic activity and a p85 subunit with an SH2 phosphotyrosine-binding domain.

Accumulation of PI 3-Phosphates in the Plasma Membrane Leads to Activation of Several Kinases

Many protein kinases become activated by binding to phosphatidyl inositol 3-phosphates in the plasma membrane. In turn, these kinases affect the activity of many cellular proteins. One important kinase that binds to PI 3-phosphates is **protein kinase B (PKB)**, a serine/threonine kinase that is also called **Akt**. Besides its kinase domain, protein kinase B also contains a *PH domain*, a conserved protein domain present in a wide variety of signaling proteins that binds with high affinity to the 3-phosphates in both PI 3,4-bisphosphate and PI 3,4,5-trisphosphate. Since these inositol phosphates are present on the cytosolic face of the plasma membrane, binding recruits the entire protein to the cell membrane. In unstimulated, resting cells, the level of these phosphoinositides (collectively called PI 3-phosphates) is low, and protein kinase B is present in the cytosol in an inactive form (Figure 16-26). Following hormone stimulation and the resulting rise in PI 3-phosphates, protein kinase B binds to these membrane-bound molecules via its PH domain and becomes localized at the plasma membrane. Binding of protein kinase B to PI 3-phosphates not only recruits the enzyme to the plasma membrane but also releases inhibition of the catalytic site by the PH domain. However, maximal activation of protein kinase B depends on recruitment of two other kinases, named PDK1 and PDK2.

PDK1 is recruited to the plasma membrane via binding of its own PH domain to PI 3-phosphates. Both membrane-associated protein kinase B and PDK1 diffuse randomly in the plane of the membrane, eventually bringing them close enough together so that PDK1 can phosphorylate protein

kinase B on a critical threonine residue in its activation lip—yet another example of kinase activation by phosphorylation. Phosphorylation of a second serine, not in the lip segment, by PDK2 is necessary for maximal protein kinase B activity (Figure 16-26). Similar to the regulation of Raf activity (see Figure 16-20), release of an inhibitory domain and phosphorylation by other kinases regulate the activity of protein kinase B.

FIGURE 16-26 Recruitment and activation of protein kinase B (PKB) in PI-3 kinase pathways. In unstimulated cells (**1**), PKB is in the cytosol with its PH domain bound to the catalytic kinase domain, inhibiting its activity. Hormone stimulation leads to activation of PI-3 kinase and subsequent formation of phosphatidylinositol (PI) 3-phosphates (see Figure 16-25). The 3-phosphate group serves as docking sites on the plasma membrane for the PH domain of PKB (**2**) and another kinase, PDK1. Full activation of PKB requires phosphorylation both in the activation lip by PDK1 and at the C-terminus by a second kinase, PDK2 (**3**). [Adapted from A. Tokar and A. Newton, 2000, *Cell* **103**:185, and S. Sarbassov et al., 2005, *Curr. Opin. Cell Biol.* **17**:596.]

Activated Protein Kinase B Induces Many Cellular Responses

Once fully activated, protein kinase B can dissociate from the plasma membrane and phosphorylate its many target proteins throughout the cell, which have a wide range of effects on cell behavior. Activation of PKB takes only 5 to 10 minutes, yet its effects can last as long as several hours.

In many cells, activated protein kinase B directly phosphorylates and inactivates pro-apoptotic proteins such as Bad, a short-term effect that prevents activation of an apoptotic pathway leading to cell death (see Figure 21-38). Activated protein kinase B also promotes survival of many cultured cells by phosphorylating the Forkhead transcription factor FOXO3a on multiple serine/threonine residues, thereby reducing its ability to induce expression of several pro-apoptotic genes.

In the absence of growth factors, FOXO3a is unphosphorylated and mainly localizes to the nucleus, where it activates transcription of several genes encoding pro-apoptotic proteins. When growth factors are added to the cells, protein kinase B becomes active and phosphorylates FOXO3a. This allows the cytosolic phosphoserine-binding protein 14-3-3 to bind FOXO3a and thus sequester it in the cytosol. (Recall that 14-3-3 also retains phosphorylated Raf protein in an inactive state in the cytosol; see Figure 16-20.) A FOXO3a mutant in which the three serine target residues for protein kinase B are mutated to alanines is “constitutively active” and initiates apoptosis even in the presence of activated protein kinase B. This finding demonstrates the importance of FOXO3a and protein kinase B in controlling apoptosis of cultured cells. Deregulation of protein kinase B is implicated in the pathogenesis both of cancer and diabetes, and in Section 16.7 we will see how protein kinase B, activated downstream of the insulin RTK, promotes glucose uptake and storage in muscle and liver. This is another example of one signaling pathway controlling different cellular functions in different cells.

The PI-3 Kinase Pathway Is Negatively Regulated by PTEN Phosphatase

Like virtually all intracellular signaling events, phosphorylation by PI-3 kinase is reversible. The relevant phosphatase, termed *PTEN phosphatase*, has an unusually broad specificity. Although PTEN can remove phosphate groups attached to serine, threonine, and tyrosine residues in proteins, its ability to remove the 3-phosphate from PI 3,4,5-trisphosphate is thought to be its major function in cells. Overexpression of PTEN in cultured mammalian cells promotes apoptosis by reducing the level of PI 3,4,5-trisphosphate and hence the activation and anti-apoptotic effect of protein kinase B.

 The *PTEN* gene is deleted in multiple types of advanced human cancers. The resulting loss of PTEN protein contributes to the uncontrolled growth of cells. Indeed, cells lacking PTEN have elevated levels of PI 3,4,5-trisphosphate and PKB activity. Since protein kinase B exerts an anti-apoptotic effect, loss of PTEN indirectly reduces the programmed cell death that is the normal fate of many cells. In certain cells, such as neuronal stem cells, absence of PTEN not only prevents apoptosis but also leads to stimulation of cell cycle progression and an enhanced rate of proliferation. Knockout mice lacking PTEN have big brains with an excess numbers of neurons, attesting to PTEN’s importance in control of normal development. ■

KEY CONCEPTS of Section 16.3

Phosphoinositide Signaling Pathways

- Many RTKs and cytokine receptors can initiate the IP₃/DAG signaling pathway by activating phospholipase C_γ (PLC_γ), a different PLC isoform than the one activated by G protein-coupled receptors.

- Activated RTKs and cytokine receptors also can initiate another phosphoinositide pathway by binding a PI-3 kinase, thereby allowing the enzyme access to its membrane-bound phosphoinositide substrates, which then become phosphorylated at the 3 position (PI 3-phosphates; see Figure 16-26).
- The PH domain in various proteins binds to PI 3-phosphates, forming signaling complexes associated with the cytosolic face of the plasma membrane.
- Protein kinase B (PKB) becomes partially activated by binding to PI 3-phosphates with its PH domain. Full activation of PKB requires phosphorylation by another kinase, PDK1, which also is recruited to the membrane by binding to PI 3-phosphates and by a second kinase, PDK2 (see Figure 16-26).
- Activated protein kinase B promotes survival of many cells by directly phosphorylating and inactivating several pro-apoptotic proteins and by phosphorylating and inactivating the FOXO3a transcription factor, which otherwise induces synthesis of pro-apoptotic proteins.
- Signaling via the PI-3 kinase pathway is terminated by the PTEN phosphatase, which hydrolyzes the 3-phosphate in PI 3-phosphates. Loss of PTEN, a common occurrence in human tumors, promotes cell survival and proliferation.

16.4 Receptor Serine Kinases That Activate Smads

We have seen how many receptors activate kinases that phosphorylate target proteins on tyrosine residues and activate a conserved set of signal transduction pathways. We have also seen how several cytosolic kinases that phosphorylate target proteins on serine or threonine become activated and function in signaling pathways; these include PKA, PKB, and PKC family members as well as MAP kinases. In this section, we discuss an evolutionarily conserved family of receptor serine kinases (the TGF- β receptor superfamily) and the conserved large family of signaling molecules (the TGF- β superfamily) that binds to them. These receptors phosphorylate and thus trigger the activation of one conserved class of transcription factors (the Smads) that regulate several growth and differentiation pathways. In unstimulated cells, Smads are in the cytosol, but when activated, they move into the nucleus to regulate transcription. The TGF- β pathway has widely diverse effects in different types of cells because different members of the TGF- β superfamily activate different members of the TGF- β receptor family, which activate different members of the Smad class of transcription factors. In addition, as we've seen with other receptor-activated transcription factors such as the STATs, the same activated Smad protein will partner with different transcription factors in different cell types and thus activate different sets of genes in these cells.

The **transforming growth factor β (TGF- β)** superfamily includes a number of related extracellular signaling mole-

cules that play widespread roles in regulating development in both invertebrates and vertebrates. The founding member of the TGF- β superfamily, TGF- β 1, was identified on the basis of its ability to induce a malignant phenotype in several cultured early stage cancerous mammalian cell lines ("transforming growth factor"); in this case TGF- β 1 promoted metastases, the spreading and invasion of primary tumors, which is discussed in Chapter 24. However, the principal function of all three human TGF- β isoforms, TGF- β 1, 2, and 3, on most normal (non-cancerous) mammalian cells is to potently prevent their proliferation by inducing synthesis of proteins that inhibit the cell cycle. TGF- β is produced by many cells in the body and inhibits growth both of the secreting cell (autocrine signaling) and neighboring cells (paracrine signaling). Loss of TGF- β receptors or any of several intracellular signal transduction proteins in the TGF- β pathway releases cells from this growth inhibition and occurs frequently in early development of human tumors. TGF- β proteins also promote expression of cell-adhesion molecules and extracellular-matrix molecules, which play important roles in tissue organization (see Chapter 20). A *Drosophila* homolog of TGF- β , called Dpp protein, participates in dorsal-ventral patterning in fly embryos. Other mammalian members of the TGF- β superfamily, the activins and inhibins, affect early development of the genital tract.

Another member of this superfamily, *bone morphogenetic protein (BMP)*, initially was identified by its ability to induce bone formation in cultured cells. Now called BMP7, it is used clinically to strengthen bone after severe fractures. Of the numerous BMP proteins subsequently recognized, many induce key steps in development, including formation of mesoderm and the earliest blood-forming cells. Most have nothing to do with bones.

Most animal cell types produce and secrete members of the TGF- β superfamily in an inactive form that is stored nearby attached to specialized cell-surface molecules or in the extracellular matrix. Release of the active form from the matrix by protease digestion or inactivation of an inhibitor leads to quick activation of the signaling molecules already in place—an important feature of many signaling pathways. The monomeric form of TGF- β growth factors contains three conserved intramolecular disulfide linkages. An additional cysteine in the center of each monomer links TGF- β monomers into functional homodimers and heterodimers (Figure 16-27).

Three Separate TGF- β Receptor Proteins Participate in Binding TGF- β and Activating Signal Transduction

Researchers soon identified TGF- β 1 as a key growth inhibitory factor, but to understand the way it worked, they had to find the receptors to which it bound. The logic of how they went about their search is representative of typical biochemical approaches to identifying receptors (see Section 15.2). Investigators first reacted the purified growth factor with the radioisotope iodine-125 (^{125}I) under conditions such that the

Mature dimeric TGF- β

FIGURE 16-27 Structure of TGF- β superfamily of signaling molecules. In this ribbon diagram of a mature TGF- β dimer, the two subunits are shown in green and blue. Disulfide-linked cysteine residues (yellow and red) are shown in ball-and-stick form. The three intrachain disulfide linkages (red) in each monomer form a cystine-knot domain, which is resistant to degradation. [From S. Daopin et al., 1992, *Science* 257:369.]

iodine covalently bonds to exposed tyrosine residues—effectively tagging them with a radioactive label. The ^{125}I -labeled TGF- β protein was incubated with cultured cells, and the incubation mixture then was treated with a chemical agent that covalently cross-linked the labeled TGF- β to its receptors on the cell surface. Purification of the ^{125}I -labeled TGF- β -receptor complexes revealed three different polypeptides with molecular weights of 55, 85, and 280 kDa, referred to as types RI, RII, and RIII TGF- β receptors, respectively.

Figure 16-28 (steps 1 and 2) depicts the relationship and function of the three TGF- β receptor proteins. The most abundant, RIII, also called β -glycan, is a cell-surface proteoglycan. A proteoglycan consists of a protein bound to glycosaminoglycan (GAG) chains such as heparin sulfate and chondroitin sulfate (see Figure 20-31). RIII, a transmembrane protein, binds and concentrates mature TGF- β molecules near the cell surface, facilitating their binding to RII receptors. The type I and type II receptors are dimeric transmembrane proteins with serine/threonine kinases as part of their cytosolic domains. RII exhibits *constitutive* kinase activity; that is, it is active even when not bound to TGF- β . Binding of TGF- β induces the formation of complexes containing two copies each of RI and RII, yet another example of ligand-induced oligomerization of cell-surface receptors. An RII subunit then phosphorylates serine and threonine residues in a highly conserved sequence of the RI subunit adjacent to the cytosolic face of the plasma membrane, thereby activating the RI kinase activity.

Activated TGF- β Receptors Phosphorylate Smad Transcription Factors

Researchers identified the transcription factors downstream from TGF- β receptors from studies of *Drosophila* mutants. These transcription factors in *Drosophila* and the related

vertebrate proteins are now called **Smads**. Three types of Smad proteins function in the TGF- β signaling pathway: *R-Smads* (receptor-regulated Smads; Smads 2 and 3), *co-Smads* (Smad4), and *I-Smads* (inhibitory Smads).

As illustrated in Figure 16-28, an R-Smad (Smad2 or Smad3) contains two domains, termed MH1 and MH2, separated by a flexible linker region. The N-terminal MH1 domain contains the specific DNA-binding segment and also a domain called the *nuclear-localization signal* (NLS). NLSs are present in virtually all transcription factors found in the cytosol and are required for their transport into the nucleus (see Chapter 13). However, when R-Smads are in their inactive, nonphosphorylated state, the NLS is masked and the MH1 and MH2 domains associate in such a way that they cannot bind to DNA or to a co-Smad. Phosphorylation of three serine residues near the C-terminus of an R-Smad by activated type I TGF- β receptors separates the domains, permitting binding of an importin (see Figure 13-36) to the NLS, which allows entrance of the Smad into the nucleus.

Simultaneously two of the phosphorylated serines in each Smad3 that were added by the RI receptor kinase bind to phosphoserine-binding sites in the MH2 domains in a Smad3 and a Smad4, forming a stable complex containing two molecules of Smad3 (or Smad2) and one molecule of a co-Smad (Smad4). The bound importin then mediates translocation of the heteromeric R-Smad/co-Smad complex into the nucleus. After importin dissociates inside the nucleus, the Smad3/Smad4 (or Smad2/Smad4) complex binds to other transcription factors to activate transcription of specific target genes.

Within the nucleus, R-Smads are continuously being dephosphorylated by a nuclear phosphatase, which results in the dissociation of the R-Smad/co-Smad complex and export of these Smads from the nucleus. Because of this continuous nucleocytoplasmic shuttling of the Smads, the concentration of active Smads within the nucleus closely reflects the levels of activated TGF- β receptors on the cell surface.

Virtually all mammalian cells secrete at least one TGF- β isoform, and most have TGF- β receptors on their surface. However, because different types of cells contain different sets of transcription factors to which the activated Smads can bind, the cellular responses induced by TGF- β vary among cell types. In epithelial cells and fibroblasts, for example, TGF- β induces expression of extracellular-matrix proteins (e.g., fibronectins and collagens; see Chapter 20) and proteins that inhibit serum proteases, which otherwise would degrade these extracellular-matrix proteins. This inhibition stabilizes the matrix, allowing cells to form stable tissues. The inhibitory proteins include plasminogen activator inhibitor 1 (PAI-1). Transcription of the *PAI-1* gene requires formation of a complex of the transcription factor TFE3 with the R-Smad/co-Smad (Smad3/Smad4) complex and binding of all these proteins to specific sequences within the regulatory region of the *PAI-1* gene (Figure 16-28, *bottom*). By partnering with other transcription factors, a R-Smad/co-Smad complex promotes expression of genes encoding other proteins such as p15, which arrests the cell cycle at the G₁ stage and thus blocks cell proliferation (see Chapter 19).

FIGURE 16-28 TGF- β /Smad signaling pathway. Step **1a**: In some cells, TGF- β binds to the type III TGF- β receptor (RIII), which increases the concentration of TGF- β near the cell surface and also presents TGF- β to the type II receptor (RII). Step **1b**: In other cells, TGF- β binds directly to RII, a constitutively phosphorylated and active kinase. Step **2**: Ligand-bound RII recruits and phosphorylates the juxtamembrane segment of the type I receptor (RI), which does not directly bind TGF- β . This releases the inhibition of RI kinase activity that otherwise is imposed by the segment of RI between the membrane and its kinase domain. Step **3**: Activated RI then phosphorylates Smad2 or Smad 3 (shown here as Smad 2/3), causing a conformational change that unmasks its nuclear-localization signal (NLS). Step **4**: Two phosphorylated molecules of Smad 2/3 bind to a co-Smad (Smad4) molecule, which is not phosphorylated, and with an importin, forming a large cytosolic complex. Steps **5** and **6**: After the entire complex translocates into the nucleus, Ran-GTP causes dissociation of the importin as discussed in Chapter 13. Step **7**: A nuclear transcription factor (e.g., TFE3) then associates with the Smad2/3/Smad4 complex, forming an activation complex that cooperatively binds in a precise geometry to regulatory sequences of a target gene. Step **8**: This complex then recruits transcriptional co-activators and induces gene transcription (see Chapter 7). Smad 2/3 is dephosphorylated by a nuclear phosphatase (step **9**) and recycles through a nuclear pore to the cytosol (step **10**), where it can be reactivated by another TGF- β receptor complex. Shown at the bottom is the activation complex for the gene encoding plasminogen activator inhibitor (PAI-1), and similar transcription complexes activate expression of genes encoding other extracellular matrix proteins such as fibronectin. [See A. Moustakas and C.-H. Heldin, 2009, *Development* **136**:3699, and D. Clarke and X. Liu, 2008, *Trends Cell Biol.* **18**:430.]

BMP proteins, which also belong to the TGF- β superfamily, bind to and activate a different set of receptors that are similar to the TGF- β RI and RII proteins but phosphorylate other R-Smads. Two of these phosphorylated Smads then form a trimeric complex with Smad4, and this Smad complex activates different transcriptional responses than those induced by the TGF- β receptor.

Loss of TGF- β signaling plays a key role in early development of many cancers. Many human tumors contain inactivating mutations in either TGF- β receptors or Smad proteins and thus are resistant to growth inhibition by TGF- β (see Figure 24-24). Most human pancreatic cancers, for instance, contain a deletion in the gene encoding Smad4 and thus cannot induce cell cycle inhibitors in response to TGF- β . In fact,

FIGURE 16-29 Model of Ski-mediated down-regulation of Smad transcription-activating function. Ski represses Smad function by binding directly to Smad4. Since the Ski-binding domain on Smad4 significantly overlaps with the Smad4 MH2 domain required for binding the phosphorylated tail of Smad3, binding of Ski disrupts the normal interactions between Smad3 and Smad4 necessary for transcriptional activation. In addition, Ski recruits the protein N-CoR, which binds directly to mSin3A; in turn, mSin3A interacts with histone deacetylase (HDAC), an enzyme that promotes histone deacetylation on nearby promoters, repressing gene expression (see Chapter 7). As a result of both processes, transcription activation induced by TGF- β and mediated by Smad complexes is shut down. The related protein SnoN functions similarly to Ski in repressing TGF- β signaling. [See J. Deheuninck and K. Luo, 2009, *Cell Res.* **19**:47.]

Smad4 was originally called *DPC* (deleted in pancreatic cancer). Retinoblastoma, colon and gastric cancer, hepatoma, and some T- and B-cell malignancies are also unresponsive to TGF- β growth inhibition. This loss of responsiveness correlates with loss of type I or type II TGF- β receptors; responsiveness to TGF- β can be restored by recombinant expression of the “missing” protein. Mutations in Smad2 also commonly occur in several types of human tumors. ■

Negative Feedback Loops Regulate TGF- β /Smad Signaling

In most signaling pathways, the response to a growth factor or other signaling molecule decreases with time (desensitization). This response is adaptive, preventing overreaction and making possible the fine-tuned control of cellular responses. Several intracellular proteins down-regulate TGF- β /Smad pathways, including two cytosolic proteins called *SnoN* and *Ski* (*Ski* stands for “Sloan-Kettering Cancer Institute”). These proteins were originally identified as cancer-causing oncoproteins because expression of *Ski* or *SnoN* is elevated in many cancers, including melanomas and certain breast cancers. When overexpressed in cultured primary fibroblast cells, *Ski* or *SnoN* cause abnormal cell proliferation, and down-regulation of *Ski* in pancreatic cancers reduces tumor growth. How *SnoN* and *Ski* trigger abnormal cell proliferation was not understood until years later, when they were found to bind to both the co-Smad (Smad4) and phosphory-

lated R-Smads (Smad3) after TGF- β stimulation. *SnoN* and *Ski* do not prevent formation of an R-Smad/co-Smad complex or affect the ability of a Smad complex to bind to DNA-control regions. Rather, they block transcription activation by a bound Smad complex, in part by inducing deacetylation of histones in adjacent chromatin segments. This renders the cells resistant to the growth-inhibitory effects of TGF- β (Figure 16-29). Interestingly, stimulation by TGF- β causes the rapid degradation of *Ski* and *SnoN*, but after a few hours, expression of *SnoN* becomes strongly induced via binding of the Smad2/Smad4 complex to the promoter of the *SnoN* gene. The increased levels of these proteins are thought to dampen long-term signaling effects due to continued exposure to TGF- β . This is another example of negative feedback, where a gene induced by TGF signaling, in this case *SnoN*, inhibits further signaling by TGF- β .

Among the other proteins induced after TGF- β stimulation are the I-Smads, especially Smad7. Smad7 blocks the ability of activated type I receptors (RI) to phosphorylate R-Smad proteins, and it may also target TGF- β receptors for degradation. In these ways Smad7, like *Ski* and *SnoN*, participates in a negative feedback loop: its induction inhibits intracellular signaling by long-term exposure to the stimulating hormone.

KEY CONCEPTS of Section 16.4

Receptor Serine Kinases That Activate Smads

- The transforming growth factor β (TGF- β) superfamily includes a number of related extracellular signaling molecules that play widespread roles in regulating development.
- TGF- β monomers are stored in an inactive form on the cell surface or in the extracellular matrix; release of active monomers (e.g., by protease digestion) leads to formation of functional homodimers and heterodimers.
- TGF- β receptors consist of three types (RI, RII, RIII). Binding of members of the TGF- β superfamily to the RII receptor kinase allows RII to phosphorylate the cytosolic domain of the RI receptor and activate its intrinsic serine/threonine kinase activity. RI then phosphorylates an R-Smad, exposing a nuclear-localization signal (see Figure 16-28).
- After phosphorylated R-Smads bind a co-Smad, the resulting complex translocates into the nucleus, where it interacts with various transcription factors to induce expression of target genes (see Figure 16-28).
- Oncoproteins (e.g., *Ski* and *SnoN*) and I-Smads (e.g., Smad7) act as negative regulators of TGF- β signaling (Figure 16-29) by inhibiting transcription mediated by the Smad2/3/Smad4 complex.
- TGF- β signaling generally inhibits cell proliferation. Loss of various components of the signaling pathway contributes to abnormal cell proliferation and malignancy.

16.5 Signaling Pathways Controlled by Ubiquitination: Wnt, Hedgehog, and NF- κ B

All the signaling pathways discussed so far are reversible and so can be turned off relatively quickly if the extracellular signal is removed. In this section, we discuss several irreversible or only slowly reversible pathways in which a critical component—either a transcription factor or an inhibitor of a transcription factor—is ubiquitinated and then proteolytically cleaved. First we discuss signaling by **Wnts** and **Hedgehogs**, two evolutionarily conserved families of signaling proteins that play key roles in many developmental pathways and often induce expression of genes required for a cell to acquire a new identity or fate. Although Wnt and Hedgehog signaling pathways use different sets of receptors and signaling proteins, they do share similarities, which is why we group them together:

- Wnt and Hedgehog bind to receptors that are similar in structure to seven-spanning G protein-coupled receptors but do not activate G proteins.
- In the resting state, key transcription factors in both pathways are ubiquitinated and targeted for proteolytic cleavage, rendering them inactive.
- Activation of each pathway involves disassembly of large cytosolic protein complexes, inhibition of ubiquitination, and release of the active transcription factor.
- Kinases including glycogen synthase kinase 3 (GSK3) play key roles in both signaling pathways.

Next we examine the **NF- κ B pathway**, a third signaling pathway controlled by ubiquitination. In this case, an inhibitor of a transcription factor, rather than a transcription factor itself, is deactivated by ubiquitination. In the resting state, a key transcription factor termed **NF- κ B** is sequestered in the cytosol bound to an inhibitor. Several stress-inducing conditions cause ubiquitination and immediate degradation of the inhibitor, allowing cells to respond immediately and vigorously by activating gene transcription. In learning how the NF- κ B pathway is activated by one class of surface receptors, we also see a very different function of polyubiquitination: the formation of a scaffold to assemble a key signal transduction complex.

Wnt Signaling Triggers Release of a Transcription Factor from a Cytosolic Protein Complex

The components of the Wnt as well as the Hedgehog signaling pathways were elucidated mainly through genetic analysis of developmental mutants in *Drosophila* but are operative in humans as well. Mutations in these pathways are thought to trigger several types of human cancers. In fact, the first vertebrate *Wnt* gene to be discovered, the mouse *Wnt-1* gene, attracted notice because it was overexpressed in certain mammary can-

cers. Subsequent work showed that overexpression was caused by insertion of a mouse mammary tumor virus (MMTV) genome near the *Wnt-1* gene. Hence *Wnt-1* is a **proto-oncogene**, a normal cellular gene whose inappropriate expression promotes the onset of cancer (see Chapter 24). The word *Wnt* is an amalgamation of *wingless*, the corresponding fly gene, with *int* for the retrovirus integration site in mice.

Activation of the *Wnt pathway* controls numerous critical developmental events, such as brain development, limb patterning, and organogenesis. A major role for Wnt signaling in bone formation was revealed by the finding that inactivating mutations in Wnt pathway components affects bone density in humans. Wnt signaling is now known to control formation of osteoblasts (bone-forming cells). Additionally, Wnt signals are important in controlling stem cells (see Chapter 21) and in many other aspects of development.

Because of the conservation of the Wnt signaling pathway in metazoan evolution, genetic studies in *Drosophila* and *C. elegans*, studies of mouse proto-oncogenes and tumor-suppressor genes, and studies of cell-junction components have all contributed to identifying various pathway components. Wnt proteins are secreted extracellular signaling molecules, which are modified by addition of a palmitate group near their N-termini. This hydrophobic group is thought to tether Wnt proteins to the plasma membrane of Wnt-secreting cells, thus limiting their range of action to adjacent cells. Wnt proteins act through two cell-surface receptor proteins: *Frizzled* (Fz), which contains seven transmembrane α helices and directly binds Wnt, and a co-receptor designated *LRP*, which appears to associate with Frizzled in a Wnt signal-dependent manner (see Figure 20-30). Mutations in the genes encoding Wnt proteins, Frizzled, or LRP (called *Arrow* in *Drosophila*) all have similar effects on the development of embryos.

According to a current model of the *Wnt pathway*, the central player in intracellular Wnt signal transduction is called **β -catenin** in vertebrates and **Armadillo** in *Drosophila*. This multi-talented protein functions both as a transcriptional activator and as a membrane-cytoskeleton linker protein (see Figure 20-13). In the absence of a Wnt signal, the β -catenin that is not attached to cell-adhesion molecules in the membrane or cytoskeleton is bound to a complex based on the scaffold protein **Axin** and containing the adenomatous polyposis coli (APC) protein, so named because its loss may result in colorectal cancer. In the resting state, two kinases in the complex, casein kinase 1 (CK1) and GSK3, sequentially phosphorylate β -catenin on multiple serine and threonine residues. Some of these phosphorylated residues serve as binding sites for a ubiquitin-ligase protein named **TrCP**. β -catenin is then ubiquitinated and rapidly degraded by the 26S proteasome (Figure 16-30a; for more on ubiquitination, see Figures 3-29 and 3-34).

The complete pathway by which Wnt signaling blocks the degradation of β -catenin has not yet been identified. We do know that Wnt binding to both Fz and LRP leads to the phosphorylation of the LRP cytosolic domain, probably by free GSK3 or CK1. This enables Axin to bind to the cytosolic do-

FIGURE 16-30 Wnt signaling pathway. (a) In the absence of Wnt, the transcription factor TCF is bound to promoters or enhancers of target genes, but its association with transcriptional repressors such as Groucho (Gro) inhibits gene activation. β-catenin is found in a complex with Axin (a scaffold protein), APC, and the kinases CK1 and GSK3, which sequentially phosphorylate β-catenin. Axin-mediated formation of this complex facilitates phosphorylation of β-catenin by GSK3 by an estimated factor of 20,000. The E3 TrCP ubiquitin ligase then binds to two of these phosphorylated β-catenin residues, leading to β-catenin ubiquitination and degradation in proteasomes. (b) Binding of Wnt to its receptor Frizzled (Fz) and to the LRP co-receptor triggers phosphorylation of LRP by GSK3 and another kinase, allowing subsequent binding of Axin. This disrupts the Axin-APC-CK1-GSK3-β-catenin complex, preventing phosphorylation of β-catenin by CK1 and GSK3 and leading to accumulation of β-catenin in the cell. After translocation to the nucleus, β-catenin binds to TCF to displace the Gro repressor and recruits Pygo, LGS, and other proteins to activate gene expression. [After R. van Amerongen and R. Nusse, 2009, *Development* **136**:3205; F. Staal and J. Sen, 2008, *Eur. J. Immunol.* **38**:1788, and E. Verheyen and C. Gottardi, 2010, *Dev. Dyn.* **239**:34. See also the Wnt Homepage, www.stanford.edu/group/nusselab/cgi-bin/wnt/.]

main of the LRP co-receptor. This shift in Axin localization disrupts the interactions that stabilize the cytosolic complex containing Axin, GSK3, CK1, and β-catenin and thus prevents phosphorylation of β-catenin by CK1 and GSK3. This in turn prevents ubiquitination and subsequent degradation of β-catenin and stabilizes it in the cytosol (Figure 16-30b). This process requires the Dishevelled (Dsh) protein, which becomes bound to the cytosolic domain of the Frizzled receptor. The freed β-catenin translocates to the nucleus, where it associates with a transcription factor (TCF) and functions as a co-activator to induce expression of particular target genes, often including those that promote cell proliferation. (Recall that TCF also functions in the MAP kinase pathway; see Figure 16-22.)

Inappropriate activation of the Wnt pathway is characteristic of many human cancers. In many tumors, the level of free β-catenin is abnormally high, and this observation provided one of the earliest clues that β-catenin can activate many growth-promoting genes. Inactivating mutations in genes encoding APC and Axin are found in multiple types of human cancers, as are mutations in β-catenin phosphorylation sites for GSK3 or CK1; these mutations reduce formation of the cytosolic complex (Figure 16-30a), reduce β-catenin degradation, and allow β-catenin to activate gene expression in the absence of the normal Wnt signal.

Among the Wnt target genes are many that also control Wnt signaling, indicating a high degree of feedback regulation. The importance of β-catenin stability and location means that Wnt signals affect a critical balance between the three pools of β-catenin in the cell: the membrane-cytoskeleton interface, cytosol, and nucleus.

In order to signal, Wnt must also bind to cell-surface proteoglycans. Evidence for the participation of proteoglycans in Wnt signaling comes from *Drosophila sugarless* (*sgl*) mutants, which lack a key enzyme needed to synthesize the GAGs heparin and chondroitin sulfate. These mutants have greatly depressed levels of Wingless (the fly Wnt protein) and exhibit other phenotypes associated with defects in Wnt signaling. How proteoglycans facilitate Wnt signaling is unknown, but perhaps binding of Wnt to specific glycosaminoglycan chains is required for it to bind to its receptor Fz or co-receptor LRP. This mechanism would be analogous to the binding of fibroblast growth factor (FGF) to heparan sulfate, which enhances binding of FGF to its receptor tyrosine kinase (see Figure 16-5).

Hedgehog Signaling Relieves Repression of Target Genes

The *Hedgehog* (*Hh*) pathway is similar to the Wnt pathway in that two membrane proteins, one with seven membrane-spanning segments, are required to receive and transduce a signal. The Hh pathway also involves disassembly of an intracellular complex containing a transcription factor, like the Wnt pathway. Unlike Wnt, the Hh protein undergoes distinctive post-translational processing, described below. Hh signaling also differs from Wnt signaling because its two membrane receptors move between the plasma membrane and intracellular vesicles, and in mammals Hh signaling is restricted to the primary cilium that protrudes from the cell surface.

Although Hedgehog is a secreted protein, it moves only a short distance from a signaling cell, on the order of 1 to 20 cells, and is bound by receptors on receiving cells. Thus Hh signals, like Wnt signals, have quite localized effects. As Hh diffuses farther and farther away from secreting cells, its concentration decreases, and different Hh concentrations induce different fates in target cells: cells that receive a large amount of Hh turn on certain genes and form certain structures; cells that receive a smaller amount turn on different genes and so form different structures. Signals that induce different cell fates depending on their concentration at their target cells are referred to as **morphogens**. During development, the production of Hedgehog and other morphogens is tightly regulated in time and space.

Processing of Hh Precursor Protein Hedgehog is formed from a precursor protein with autoproteolytic activity that enables the protein to cut itself in half. The cleavage produces an N-terminal fragment, which is subsequently secreted to signal to other cells, and a C-terminal fragment, which is degraded. As shown in Figure 16-31, cleavage of the precursor is accompanied by covalent addition of the lipid cholesterol to the new carboxyl terminus of the N-terminal fragment. The C-terminal domain of the precursor, which catalyzes these reactions, is found in other proteins and may promote similar autoproteolytic mechanisms.

A second modification to Hedgehog, the addition of a palmitoyl group to the N-terminus, makes the protein even more hydrophobic. Together, the two attached hydrophobic groups may cause secreted Hedgehog to bind nonspecifically and reversibly to cell plasma membranes, thereby limiting its diffusion and so its range of action in tissues. Spatial restriction plays a crucial role in constraining the effects of powerful signals such as Hh. Recall that the palmitoyl group also is added to Wnt proteins and likely also causes Wnt to bind reversibly to cells, thereby restricting Wnt signaling to cells adjacent to the signaling cell.

Hh Pathway in *Drosophila* Genetic studies in *Drosophila* indicate that two membrane proteins, *Smoothed* (*Smo*) and *Patched* (*Ptc*), are required to receive and transduce a Hedgehog signal to the cell interior. Smoothed has seven membrane-spanning α helices and is related in sequence to the Wnt receptor Fz. Patched is predicted to contain 12 trans-membrane α helices and is most similar structurally to the Niemann-Pick C1 (NPC1) protein, a member of the ABC superfamily of membrane proteins (see Table 11-3).

Figure 16-32 depicts a current model of the *Hedgehog* (*Hh*) pathway in *Drosophila*. Evidence supporting this model initially came from study of fly embryos with loss-of-function mutations in the *hedgehog* (*hh*) or *smoothed* (*smo*) genes. Both types of mutant embryos have very similar developmental phenotypes. Moreover, both the *hh* and *smo* genes are required to activate transcription of the same target genes (e.g., *patched* and *wingless*) during embryonic development. In contrast, loss-of-function mutations in the *patched* (*ptc*) gene produce a quite different phenotype, one similar to the

FIGURE 16-31 Processing of Hedgehog (Hh) precursor protein. Cells synthesize a 45-kDa Hh precursor, which undergoes a nucleophilic attack by the thiol side chain of cysteine 258 (Cys-258) on the carbonyl carbon of the adjacent residue glycine 257 (Gly-257), forming a high-energy thioester intermediate. An enzymatic activity in the C-terminal domain then catalyzes the formation of an ester bond between the β -3 hydroxyl group of cholesterol and glycine 257, cleaving the precursor into two fragments. The N-terminal signaling fragment (blue) retains the cholesterol moiety and is also modified by the addition of a palmitoyl group to the N-terminus. This processing is thought to occur mostly intracellularly. The two hydrophobic anchors may tether the secreted, processed Hh protein to the plasma membrane. [Adapted from J. A. Porter et al., 1996, *Science* 274:255.]

effect of flooding the embryo with Hedgehog protein. Thus Patched appears to antagonize the actions of Hedgehog and vice versa. These findings suggest that, in the absence of Hedgehog, Patched represses target genes by inhibiting a signaling pathway needed for gene activation. The additional observation that Smoothed is required for the transcription of target genes in mutants lacking *patched* function places Smoothed downstream of Patched in the Hh pathway. The evidence indicates that Hedgehog binds directly to Patched and prevents Patched from blocking Smoothed action, thus activating the transcription of target genes.

In the absence of Hedgehog, Patched is enriched in the plasma membrane, but Smoothed is in membranes lining internal vesicles. The cytosolic protein complex in the Hh

FIGURE 16-32 Hedgehog signaling in flies. (a) In the absence of hedgehog (Hh), patched (Ptc) protein inhibits smoothened (Smo), which is present largely in the membrane of internal vesicles. A complex containing Fused (Fu), a kinase; other kinases; Costal-2 (Cos2), a kinesin-related motor protein; and Cubitus interruptus (Ci), a zinc-finger transcription factor, binds to microtubules. Ci is phosphorylated in a series of steps involving protein kinase A (PKA), glycogen synthase kinase 3 (GSK3), and casein kinase 1 (CK1). The phosphorylated Ci is then proteolytically cleaved by the ubiquitin-proteasome pathway, generating the fragment Ci75, which functions as a transcriptional repressor of Hh-responsive genes. Su(Fu) may also associate with full-length Ci to prevent its translocation to the nucleus. (b) Hh binds to

Ptc, causing some Ptc to move to internal compartments (not shown) and relieving the inhibition of Smo. Smo then moves to the plasma membrane, is phosphorylated, binds Cos2, and is stabilized from degradation. Both Fu and Cos2 become extensively phosphorylated, and most importantly the Fu-Cos2-Ci complex becomes dissociated. This leads to the stabilization of a full-length, alternately modified Ci, Ci*, which displaces the repressor Ci 75 from the promoter of target genes, recruits the CREB-binding activator protein (CBP), and induces expression of target genes. The exact membrane compartments in which Ptc and Smo respond to Hh and function are unknown. [After S. Goetz and K. Anderson, 2010, *Nature Rev. Genet.* 11:331.]

pathway consists of several proteins (Figure 16-32a), including Fused (Fu), a serine-threonine kinase; Costal-2 (Cos2), a microtubule-associated kinesin-like protein; and Cubitus interruptus (Ci), a transcription factor. This complex is bound to microtubules in the cytosol. Phosphorylation of Ci by at least three kinases causes binding of a component of a ubiquitin ligase complex that in turn directs ubiquitination of Ci and its targeting to proteasomes. There Ci undergoes proteolytic cleavage; the resulting Ci fragment, designated Ci75, translocates to the nucleus and represses expression of Hh target genes.

Following binding of Hedgehog to the receptor Patched, both proteins move from the cell surface into internal vesicles while Smoothened moves from internal vesicles to the plasma membrane; the binding of Hedgehog to Patched also inhibits its ability to inhibit Smoothened (Figure 16-32a). This triggers several cellular responses, including an increase in phosphorylation of Fu and Cos2. Importantly, the complex of Fu, Cos2, and Ci dissociates from microtubules, and Cos2 becomes associated with the C-terminal tail of Smoothened. The resulting disruption of the Fus/Cos2/Ci complex causes a reduction in both phosphorylation and cleavage of Ci. As a result, a modified form of full-length Ci is generated, termed Ci*, and translocates to the nucleus, where it binds to the

transcriptional co-activator CREB-binding protein (CBP), promoting the expression of target genes.

Regulation of Hh Signaling Feedback control of the Hh pathway is important because unrestrained Hh signaling can cause cancerous overgrowth or formation of the wrong cell types. In *Drosophila*, one of the genes induced by the Hh signal is *patched*. The subsequent increase in expression of Patched antagonizes the Hh signal in large measure by reducing the pool of active Smoothened protein. Thus the system is buffered: if during development too much Hh signal is made, a consequent increase in Patched will compensate; if too little Hh signal is made, the amount of Patched is decreased.

Hedgehog Signaling in Vertebrates Involves Primary Cilia

Hh signaling pathway in vertebrates shares many features with the *Drosophila* pathway, but there are also some striking differences. First, mammalian genomes contain three *hh* genes and two *ptc* genes, which are expressed differentially among various tissues. Second, mammals express three Gli transcription factors that divide up the roles of the single Ci

protein in *Drosophila*. All other components of the Hh pathway also are conserved.

The most fascinating aspect of the mammalian Hh pathway is the newly recognized importance of primary cilia. Cilia are long plasma membrane–enveloped structures that protrude from the cell surface. The roles of the abundant cilia in the trachea in moving materials along the tracheal surface and of flagella in sperm locomotion are well known (see Chapter 18). Most cells, however, have a single immotile cilium called the *primary cilium* (Figure 16-33). As we learn in Chapter 18, cilia are extended and maintained by the transport of

proteins and particles along a bundle of microtubules in its center; different intraflagellar transport (IFT) proteins move proteins and particles from the base of the cilium to the tip and in the opposite direction. Some of the first evidence for a role of cilia in Hh signaling came from a screen for mutations that altered early mammalian development in a manner similar to that seen in embryos with altered Hh signaling: these phenotypes included loss of certain types of cells in the neural tube that require high levels of one Hh protein. Many of these mutations were in genes encoding IFT proteins, indicating a role for cilia (or flagella) in Hh signaling.

FIGURE 16-33 Hedgehog signaling in vertebrates. Hedgehog (Hh) signaling occurs in primary cilia, but otherwise the overall process is similar to that in flies. (a) In the absence of Hh, Patched is localized to the ciliary membrane and in an unknown manner blocks the entry of Smoothened into cilia; Smo is present mainly in the membrane of internal vesicles. The kinesin KIF7 (the Cos2 homolog) binds to microtubules at the cilium base, where it may form a complex with the transcription factor Gli (the vertebrate homolog of Ci), SuFu, and

kinases. KIF7 prevents Gli enrichment within the cilium and promotes proteolytic processing of Gli to the Gli repressor GliR. (b) Hh binding triggers movement of Smo to the ciliary membrane and movement of the KIF7 motor protein up the microtubule to the ciliary tip, where Gli accumulates and gets activated by an as yet unknown mechanism. Activated Gli is then transported down the cilium and is released into the cytosol. [After S. Goetz and K. Anderson, 2010, *Nature Rev. Genet.* 11:331.]

Subsequent analysis showed that, in the absence of Hh signaling, Ptc is localized to the membrane of the primary cilium and Smo is in internal vesicles near the base of the cilium (Figure 16-33a). After Hh addition, Smo becomes localized to the ciliary membrane while Ptc moves out of the ciliary membrane (Figure 16-33b). This movement of Smo involves phosphorylation of the receptor C-terminal cytosolic domain by β -adrenergic receptor kinase (BARK), the same enzyme that modifies G protein-coupled receptors. β -arrestin then binds to Smo. In turn β -arrestin recruits the microtubule motor protein Kif3A, which binds to the microtubules in the core of the cilium and moves Smo up the ciliary membrane. At the same time degradation of Gli to a repressor fragment is blocked, and the motor protein Kif7 moves Gli to the tip of the cilium. There it becomes activated by Smo by a mechanism as yet unknown, and then another motor protein, a dynein, moves the activated Gli to the base of the cilium (Figure 16-31b). As in flies, this active transcription factor then moves into the nucleus, where it can activate expression of multiple target genes.

It is not clear why during vertebrate evolution primary cilia became necessary for Hh signaling since the same result—conversion of a transcription factor from a repressor to an activator of gene expression—occurs downstream of Hh signaling in both mammalian and invertebrate systems.

 Inappropriate activation of Hh signaling is the cause of several types of human tumors, including medulloblastomas (cerebellum tumors) and rhabdomyosarcomas (muscle tumors). Primary cilia are essential for this abnormal Hh signaling, and drugs that inhibit the function of primary cilia are being tested on animal models of these cancers. For instance, expression of a mutant activated form of Smoothened in the postnatal mouse brain will cause medulloblastomas, but these tumors will not form if, simultaneously, a gene encoding an essential ciliary protein is inactivated. ■

Degradation of an Inhibitor Protein Activates the NF- κ B Transcription Factor

In the resting state of both the Wnt and Hedgehog pathways, a key transcription factor is ubiquitinated and subjected to proteolytic degradation; activation of the signaling pathway involves blockage of ubiquitination and release of the transcription factor in its active state. The NF- κ B pathway works in the opposite manner: in the resting state, the NF- κ B transcription factor is retained in the cytosol bound to an inhibitor; activation of the signaling pathway involves ubiquitination followed by degradation of the inhibitor, triggering release of the active transcription factor. This mechanism allows cells to respond to a variety of stress signals by immediately and vigorously activating gene transcription. The steps in the NF- κ B pathway were revealed in studies with both mammalian cells and *Drosophila*.

NF- κ B (an acronym for the somewhat unwieldy descriptor “nuclear-factor kappa-light-chain enhancer of activated B

cells”) is rapidly activated in mammalian immune-system cells in response to bacterial and viral infection, inflammation, and a number of other stressful situations, such as ionizing radiation. The NF- κ B pathway is activated in some cells of the immune system when components of bacterial or fungal cell walls bind to certain *Toll-like receptors* on the cell surface (see Figure 23-23). This pathway is also activated by so-called inflammatory cytokines, such as *tumor necrosis factor alpha* (TNF α) and *interleukin 1* (IL-1), which are released by nearby cells in response to infection. In all cases, binding of ligand to its receptor induces assembly of a multiprotein complex in the cytosol near the plasma membrane that triggers a signaling pathway resulting in activation of the NF- κ B transcription factor.

NF- κ B was originally discovered on the basis of its transcriptional activation of the gene encoding the light chain of antibodies (immunoglobulins) in B cells. It is now thought to be the master transcriptional regulator of the immune system in mammals. Although flies do not make antibodies, NF- κ B homologs in *Drosophila* induce synthesis of a large number of secreted antimicrobial peptides in response to bacterial and viral infection. This phenomenon indicates that the NF- κ B regulatory system has been conserved during evolution and is more than half a billion years old.

Biochemical studies in mammalian cells and genetic studies in flies have provided important insights into the operation of the NF- κ B pathway. The two subunits of heterodimeric NF- κ B (p65 and p50) share a region of homology at their N-termini that is required for their dimerization and binding to DNA. In cells that are not undergoing a stress or responding to signs of an infection, direct binding to an inhibitor called I- κ B α sequesters NF- κ B in an inactive state in the cytosol. A single molecule of I- κ B α binds to the paired N-terminal domains of the p50-p65 heterodimer, thereby masking their nuclear-localization signals (Figure 16-34a). A three-protein complex termed *I- κ B kinase* operates immediately upstream of NF- κ B and is responsible for releasing it from sequestration. The β kinase subunit of I- κ B kinase is the point of convergence of all of the extracellular signals that activate NF- κ B noted above. Within minutes of stimulation of the cell by an infectious agent or inflammatory cytokine, the IKK kinase β subunit becomes activated by phosphorylation and then phosphorylates two N-terminal serine residues on I- κ B α (Figure 16-34a, steps **1** and **2**). An E3 ubiquitin ligase then binds to these phosphoserines and polyubiquitinates I- κ B α , triggering its immediate degradation by a proteasome (steps **3** and **4**). In cells expressing mutant forms of I- κ B α in which these two serines have been changed to alanine and so cannot be phosphorylated, NF- κ B is permanently inactive, demonstrating that phosphorylation of I- κ B α is essential for pathway activation.

The degradation of I- κ B exposes the nuclear-localization signals on NF- κ B, which then translocates into the nucleus and activates transcription of a multitude of target genes (Figure 16-34a, steps **5** and **6**). Despite its activation by proteolysis, NF- κ B signaling eventually is turned off by a negative feedback loop since one of the genes whose transcription is immediately induced by NF- κ B encodes I- κ B α . The resulting

FIGURE 16-34 Activation of the NF-κB signaling pathway. (a) In resting cells, the dimeric transcription factor NF-κB, composed of p50 and p65 subunits, is sequestered in the cytosol, bound to the inhibitor I-κBα. Step 1: Activation of the trimeric I-κB kinase is stimulated by many agents, including virus infection, ionizing radiation, binding of the pro-inflammatory cytokines TNFα or IL-1 to their respective receptors, or activation of any of several Toll-like receptors by components of invading bacteria or fungi. Step 2: The β subunit of I-κB kinase then phosphorylates the inhibitor I-κBα, which then binds an E3 ubiquitin ligase. Steps 3 and 4: Subsequent lysine 48-linked polyubiquitination of I-κBα targets it for degradation by proteasomes. Step 5: The removal of I-κBα unmasks the nuclear-localization signals (NLS) in both subunits of NF-κB, allowing their translocation to the nucleus. Step 6: In the nucleus, NF-κB activates transcription of numerous target genes, including the gene encoding I-κBα, which acts to terminate signaling, and genes encoding various inflammatory cytokines. (b) Binding of interleukin-1β (IL-1β) to IL-1 receptors (IL-1R) triggers receptor oligomerization and recruitment of several proteins to the receptor cytosolic domain, including TRAF6, an E3 ubiquitin ligase, which catalyzes synthesis of long lysine-63-linked polyubiquitin chains linked to TRAF6 and other proteins in the complex. The polyubiquitin chains function as a scaffold to recruit the kinase TAK1 and the NEMO subunit of the trimeric I-κB kinase complex. TAK1 then phosphorylates itself and the β subunit of I-κB kinase, activating its kinase activity and enabling it to phosphorylate I-κBα. [Part (a) after R. Khush et al., 2001, *Trends Immunol.* **22**:260, and J-L Luo et al., 2005, *J. Clin. Invest.* **115**:2625; part (b) after B. Skaug et al., 2009, *Ann. Rev. Biochem.* **78**:769.]

increased levels of the I- κ B α protein bind active NF- κ B in the nucleus and return it to the cytosol.

In many immune-system cells, NF- κ B stimulates transcription of more than 150 genes, including those encoding cytokines and chemokines; the latter attract other immune-system cells and fibroblasts to sites of infection. NF- κ B also promotes expression of receptor proteins that enable neutrophils (a type of white blood cell) to migrate from the blood into the underlying tissue (see Figure 20-39). In addition, NF- κ B stimulates expression of iNOS, the inducible isoform of the enzyme that produces nitric oxide, which is toxic to bacterial cells, as well as expression of several anti-apoptotic proteins, which prevent cell death. Thus this single transcription factor coordinates and activates the body's defense either directly by responding to pathogens and stress or indirectly by responding to signaling molecules released from other infected or wounded tissues and cells.

Polyubiquitin Chains Serve as Scaffolds Linking Receptors to Downstream Proteins in the NF- κ B Pathway

Above we saw that the β kinase subunit of I- κ B is the point of convergence for extracellular signals transmitted through multiple receptors, including Toll and IL-1 receptors. Since the cytosolic domains of the Toll and IL-1 receptors have no enzymatic activity, it was a mystery for many years how activation of these receptors led to phosphorylation and activation of the β kinase subunit of I- κ B. Early work showed that the presence of IL-1 led to oligomerization of the IL-1 receptor and binding of several proteins to its cytosolic domain, including TRAF6, an E3 ubiquitin ligase that synthesizes polyubiquitin chains. Since all polyubiquitination was then thought to signal degradation by proteasomes, researchers looked for ubiquitinated target proteins that were quickly destroyed. Not finding these, scientists looked for other possible roles for polyubiquitin and soon found that depending on the specific E3 ubiquitin ligase, ubiquitin forms multiple types of polymers that have different structures and biological functions.

The E3 ubiquitin ligase that modifies I- κ B α links the carboxyl terminus of one ubiquitin to lysine 48 (K48) on another; this poly-K48 ubiquitin targets the attached protein to the proteasome (Figure 16-36a). The E3 ligase TRAF6, in contrast, links the carboxyl terminus of one ubiquitin to lysine 63 (K63) on another (see Figure 3-34). The resultant poly-K63 ubiquitin chain does not target proteins for degradation; rather, these ubiquitin chains act as scaffolds that bind proteins with a *poly-K63 ubiquitin-binding domain*. One of these is the protein kinase TAK1, which becomes activated by binding to the polyubiquitin chain; another is the NEMO subunit of I- κ B kinase. Binding to poly-K63 ubiquitin thus brings the kinase and its target, the β kinase subunit of I- κ B kinase, into proximity so that TAK1 can phosphorylate and activate this downstream kinase (Figure 16-36b). As noted above, this kinase then phosphorylates I- κ B α . Thus

different types of polyubiquitin chains participate in very different ways in transmitting the IL-1 signal to activation of the NF- κ B transcription factors.

KEY CONCEPTS of Section 16.5

Signaling Pathways Controlled by Ubiquitination: Wnt, Hedgehog, and NF- κ B

- Many signaling pathways involve ubiquitination and proteolysis of target protein and so are irreversible or only slowly reversible. Target proteins can be either a transcription factor or an inhibitor of a transcription factor.
- Wnt controls numerous critical developmental events, such as brain development, limb patterning, and organogenesis. Hedgehog functions as a morphogen during development. Activating mutations in both pathways can cause cancer.
- Both Hedgehog and Wnt are secreted proteins that contain lipid anchors that tether them to cell membranes, thereby reducing their signaling ranges.
- Wnt signals act through two cell-surface proteins, the receptor Frizzled and co-receptor LRP, and an intracellular complex containing β -catenin (see Figure 16-30). Binding of Wnt promotes the stability and nuclear localization of β -catenin, which either directly or indirectly promotes activation of the TCF transcription factor.
- The Hedgehog signal also acts through two cell-surface proteins, Smoothened and Patched, and an intracellular complex containing the Cubitus interruptus (Ci) transcription factor (see Figure 16-32). An activating form of Ci is generated in the presence of Hedgehog; a repressing Ci fragment is generated in the absence of Hedgehog. Both Patched and Smoothened change their subcellular location in response to Hedgehog binding to Patched.
- Hh signaling in vertebrates requires primary cilia and intraflagellar transport proteins. Patched localizes to the ciliary membrane in the absence of Hh and Smo moves to cilia when Hh is present (see Figure 16-33).
- The NF- κ B transcription factor regulates many genes that permit cells to respond to infection and inflammation.
- In unstimulated cells, NF- κ B is localized to the cytosol, bound to the inhibitor protein I- κ B α . In response to many types of extracellular signals, phosphorylation-dependent ubiquitination and degradation of I- κ B α in proteasomes releases active NF- κ B, which translocates to the nucleus (see Figure 16-34a).
- Polyubiquitin chains linked to the activated IL-1 receptor form a scaffold that brings the TAK1 kinase near its substrate, a subunit of the I- κ B kinase, and thus allows signals to be transmitted from the receptor to downstream components of the NF- κ B pathway (see Figure 16-34b).

16.6 Signaling Pathways Controlled by Protein Cleavage: Notch/Delta, SREBP

In this section, we consider signaling pathways activated by protein cleavage in an extracellular space—often at the surface of the cell—generally by members of the *matrix metalloprotease (MMP) family*. In the *Notch/Delta pathway*, for instance, MMP cleavage of the extracellular part of the Notch receptor is followed by its cleavage within the plasma membrane by a different protease, releasing the cytosolic domain that functions as a transcription factor. This pathway determines the fates of many types of cells during development.

Earlier in the chapter, we saw that multiple growth factors signal through receptor tyrosine kinases. Many such growth factors, including members of the epidermal growth factor (EGF) family, are made as membrane-spanning precursors and can signal adjacent cells by binding to EGF receptors on their surfaces. But cleavage of these proteins by matrix metalloproteases releases the active growth factors into the extracellular medium, allowing them to signal cells much farther away and even the releasing cells themselves (autocrine signaling). Since this process involves a form of proteolytic cleavage similar to that which occurs in the Notch/Delta pathway, we consider it here as well. Activation and release of growth factors by protein cleavage goes awry in many cancers and may lead to an often-fatal enlargement of the heart. Inappropriate MMP cleavage of yet another membrane-spanning protein has been implicated in the pathology of Alzheimer's disease.

Regulated protein cleavage is also used in some *intracellular* signaling pathways. Thus we conclude our discussion by describing one such pathway: the intramembrane cleavage of a transcription factor precursor within the Golgi membrane in response to low cholesterol levels. This pathway is essential for maintaining the proper balance of cholesterol and phospholipids for constructing cell membranes (see Chapter 10).

On Binding Delta, the Notch Receptor Is Cleaved, Releasing a Component Transcription Factor

Both the receptor called Notch and its ligand Delta are single-spanning transmembrane proteins found on the cell surface. Notch also has other ligands, but the molecular mechanisms of activation are the same with each ligand. Delta on one cell binds to Notch on an adjacent cell (but not on the same cell), activating Notch so that it undergoes two cleavage events; these result in release of the Notch cytosolic domain, which functions as a transcription factor.

Notch protein is synthesized as a monomeric membrane protein in the endoplasmic reticulum. In the Golgi complex, it undergoes a proteolytic cleavage that generates an extracellular subunit and a transmembrane-cytosolic subunit; the two subunits remain noncovalently associated with each other. Following binding of Delta, the Notch protein on the responding cell undergoes two additional proteolytic cleavages in a proscribed order (Figure 16-35). The first is catalyzed by ADAM 10, a matrix metalloprotease. (The name ADAM stands for a *disintegrin and metalloprotease*; a disintegrin is a conserved

FIGURE 16-35 Notch/Delta signaling pathway. In the absence of Delta, the extracellular subunit of Notch on a responding cell is noncovalently associated with its transmembrane-cytosolic subunit. When Notch binds to its ligand Delta on an adjacent signaling cell (step 1), Notch is first cleaved by the matrix metalloprotease ADAM 10, which is bound to the membrane, releasing the extracellular Notch segment (step 2). Next the nicastrin subunit of the four protein γ -secretase complex binds to the stump generated by ADAM 10, and the presumed protease, presenilin 1, catalyzes an intramembrane cleavage that releases the cytosolic segment of Notch (step 3). Following translocation to the nucleus, this Notch segment interacts with several transcription factors to affect expression of genes that in turn influence the determination of cell fate during development (step 4). [See M. S. Brown et al., 2000, *Cell* 100:391, and D. Seals and S. Courtneidge, 2003, *Genes Dev.* 17:7.]

protein domain that binds integrins and disrupts cell-matrix interactions—see Chapter 20.) The second cleavage occurs within the hydrophobic membrane-spanning region of Notch and is catalyzed by a four-protein transmembrane complex termed γ -secretase. This cleavage releases the Notch cytosolic segment, which immediately translocates to the nucleus, where it affects transcription of various target genes. How peptide bond hydrolysis can occur within a hydrophobic intramembrane environment is not well understood. Such signal-induced *regulated intramembrane proteolysis (RIP)* is used in a variety of signaling systems, including the response of cells to low cholesterol (see below) and to the presence of unfolded proteins in the endoplasmic reticulum (see Chapter 13).

The γ -secretase complex contains a protein termed *presenilin 1* and three other essential subunits, *aph-1*, *pen-2*, and *nicastrin*. Presenilin 1 (PS1) was first identified as the product of a gene that commonly is mutated in patients with an early-onset autosomal dominant form of Alzheimer's disease. Studies on cells lacking nicastrin revealed why γ -secretase can only cleave proteins that have first been cleaved by an ADAM or other matrix metalloprotease. Nicastrin binds to the N-terminal extracellular stump of the membrane protein that is generated by the first protease (see Figure 16-35). Without this stump, nicastrin and thus the entire γ -secretase complex cannot interact with its target protein. We examine the role of ADAM proteins and γ -secretase in the development of Alzheimer's disease below.

The location of Notch and Delta in different, adjacent cells is essential because they participate in a highly conserved and important cell differentiation process in both invertebrates and vertebrates, called *lateral inhibition*. In this process, adjacent and initially developmentally equivalent cells assume completely different fates. In effect, one cell in a group of equivalent cells instructs the others around it to choose a different fate. As an example of how this occurs, in *Drosophila*, the released intracellular segment of Notch forms a complex with a

DNA-binding protein called Suppressor of Hairless, or Su(H). This complex stimulates transcription of many genes whose net effect is to influence the determination of cell fate during development. One of the proteins increased in this manner is Notch itself, and Delta production is correspondingly reduced. Thus a cell that happens to have a bit more Notch than its neighbors will be stimulated to produce yet more Notch and less Delta and so assume a developmental fate different from the Delta-rich adjacent cells. Reciprocal regulation of the receptor and ligand in this fashion is an essential feature of the interaction between initially equivalent cells that causes them to assume different cell fates.

Matrix Metalloproteases Catalyze Cleavage of Many Signaling Proteins from the Cell Surface

Many signaling molecules are synthesized as transmembrane proteins whose signal domain extends into the extracellular space. Such signaling proteins, like Delta described above, are often biologically active but can signal only by binding to receptors on adjacent cells. However, many growth factors and other protein signals are synthesized as transmembrane precursors whose cleavage releases the soluble, active signaling molecule into the extracellular space. This cleavage is often carried out by matrix metalloproteases (MMP), which are metal-containing enzymes that cleave the extracellular segments of target proteins near the outer surface of the plasma membrane. The human genome encodes 19 metalloproteases in the ADAM family, and many are involved in cleaving the precursors of signaling proteins just outside their transmembrane segment. This ADAM-mediated proteolysis of such precursors is similar to the cleavage of Notch by ADAM 10 (see Figure 16-35) except that the released extracellular segment has signaling activity. ADAM activity and hence the release of active signaling proteins must be tightly regulated by the cell, but how this happens is not yet

FIGURE 16-36 Proteolytic cleavage of APP and Alzheimer's disease. (Left) Sequential proteolytic cleavage by α -secretase (ADAM 10 or ADAM 17) (1) and γ -secretase (2) produces an innocuous membrane-embedded peptide of 26 amino acids. (Right) Cleavage in the extracellular domain by β -secretase (1) followed by cleavage within the membrane by γ -secretase (2) generates the 42-residue

$A\beta_{42}$ peptide, which spontaneously forms oligomers, and then the larger amyloid plaques found in the brain of patients with Alzheimer's disease. In both pathways, the cytosolic segment of APP is released into the cytosol, but its function is not known. [See S. Lichtenthaler and C. Haass, 2004, *J. Clin. Invest.* **113**:1384, and V. Wilquet and B. De Strooper, 2004, *Curr. Opin. Neurobiol.* **14**:582. Inset © ISM/Phototake.]

clear. A breakdown in the mechanisms for regulating ADAM proteases can lead to abnormal cell proliferation.

 Medically important examples of the regulated cleavage of signal protein precursors are members of the EGF family, including EGF, HB-EGF, TGF- α , NRG1, and NRG2 (see Figure 16-7). The increased activity of one or more ADAMs that is seen in many cancers can promote cancer development in two ways. First, heightened ADAM activity can lead to high levels of extracellular EGF family growth factors that stimulate secreting cells (autocrine signaling) or adjacent cells (paracrine signaling) to proliferate inappropriately. Second, by destroying components of the extracellular matrix, increased ADAM activity is thought to facilitate metastasis, the movement of tumor cells to other sites in the body.

ADAM proteases also are an important factor in heart disease. As we learned in the last chapter, epinephrine (adrenaline) stimulation of β -adrenergic receptors in heart muscle causes glycogenolysis and an increase in the rate of muscle contraction. Prolonged treatment of heart muscle cells with epinephrine, however, leads to activation of ADAM 9 by an unknown mechanism. This matrix metalloprotease cleaves the transmembrane precursor of HB-EGF. The released HB-EGF then binds to EGF receptors on the signaling heart muscle cells and stimulates their inappropriate growth. This excessive proliferation can lead to an enlarged but weakened heart—a condition known as cardiac hypertrophy, which may cause early death. ■

Inappropriate Cleavage of Amyloid Precursor Protein Can Lead to Alzheimer's Disease

 Alzheimer's disease is another disorder marked by the inappropriate activity of matrix metalloproteases. A major pathologic change associated with Alzheimer's disease is accumulation in the brain of *amyloid plaques* containing aggregates of a small (42 residue-containing) peptide termed $A\beta_{42}$. This peptide is derived by proteolytic cleavage of *amyloid precursor protein* (APP), a transmembrane cell-surface protein of still mysterious function expressed by neurons.

Like Notch protein, APP undergoes one extracellular cleavage and one intramembrane cleavage (Figure 16-36). First, the extracellular domain is cleaved at one of two sites in the extracellular domain: by ADAM10 (often collectively called α -secretase) or by another matrix protease termed β -secretase. In either case, γ -secretase then catalyzes a second cleavage at a single intramembrane site, releasing the same APP cytosolic domain but different small peptides, depending on which extracellular site was cleaved. The pathway initiated by α -secretase generates a 26-residue peptide that apparently does no harm. In contrast, the pathway initiated by β -secretase generates the pathologic $A\beta_{42}$ peptide, which spontaneously forms oligomers and then the larger amyloid plaques found in the brain of patients with Alzheimer's disease.

APP was recognized as a major player in Alzheimer's disease through a genetic analysis of the small percentage of pa-

tients with a family history of the disease. Many had mutations in the APP protein, and intriguingly these mutations are clustered around the cleavage sites of α -, β -, or γ -secretase depicted in Figure 16-36. Other cases of familial Alzheimer's disease involve missense mutations in presenilin 1, a subunit of γ -secretase that enhances the formation of the $A\beta_{42}$ peptide, leading to plaque formation and eventually to the death of neurons.

At one time chemical inhibitors of γ -secretase activity were proposed as ideal therapeutics for treatment of Alzheimer's disease, but as might be expected, they had many severe side effects due to the concomitant inhibition of cleavage of Notch and other transmembrane proteins. The recently discovered *γ -secretase-activating protein* (GSAP) drastically and selectively increases amyloid $A\beta_{42}$ production through a mechanism involving its interactions with both γ -secretase and its substrate, the APP carboxy-terminal fragment generated by β -secretase. Since GSAP does not affect cleavage of Notch by γ -secretase, chemicals that bind selectively to GSAP and inhibit its interactions with γ -secretase or its substrate, the APP carboxy-terminal fragment, offer promise as Alzheimer therapeutics. ■

Regulated Intramembrane Proteolysis of SREBP Releases a Transcription Factor That Acts to Maintain Phospholipid and Cholesterol Levels

Although this chapter is focused on signaling pathways initiated by extracellular molecules (e.g. growth factors), *intracellular* signaling pathways that sense the levels of internal molecules and respond accordingly sometimes share principles of molecular regulation and even mechanisms with pathways initiated from outside the cell. One such case is the control of cellular membrane lipids. A cell would soon face a crisis if it did not have enough phospholipids to make adequate amounts of membranes or had so much cholesterol that large crystals formed and damaged cellular structures. Cells sense the relative amounts of cholesterol and phospholipids in their membranes; they respond by adjusting the rates of cholesterol biosynthesis and import so that the cholesterol:phospholipid ratio is kept within a narrow desirable range. Regulated intramembrane proteolysis, which occurs in the Notch pathway, also plays an important role in this cellular response to altered cholesterol levels.

As we learned in Chapter 14, low-density lipoprotein (LDL) is rich in cholesterol and functions in transporting this lipid through the aqueous circulatory system (see Figure 14-27). Both the cholesterol biosynthetic pathway (see Figure 10-26) and cellular levels of LDL receptors that mediate cellular uptake of LDL are down-regulated when cellular cholesterol levels are adequate. Since LDL is imported into cells via receptor-mediated endocytosis (see Figure 14-29), a decrease in the number of LDL receptors leads to reduced cellular import of cholesterol. Both cholesterol biosynthesis and import are regulated at the level of gene transcription. For

example, when growing cultured cells that need new membrane for sustained division are incubated with an external source of cholesterol, for example, LDL added to the culture medium, the level and the activity of HMG-CoA reductase, the rate-controlling enzyme in cholesterol biosynthesis, is suppressed, whereas the activity of acyl:cholesterol acyl transferase (ACAT), which converts cholesterol into the esterified storage form, is increased. Thus energy is not wasted making unnecessary additional cholesterol and cholesterol homeostasis is achieved.

Genes whose expression is controlled by the level of sterols such as cholesterol often contain one or more 10-base-pair *sterol regulatory elements* (SREs), or SRE half-sites, in their promoters. (These SREs differ from the serum response elements that control many early response genes, discussed in Section 16.2.) The interaction of cholesterol-dependent transcription factors called **SRE-binding proteins** (SREBPs) with these response elements modulates the expression of the target genes. How do cells sense how much cholesterol they have and how

is this “signal” used to control the level of SREBPs in the nucleus and thus gene expression? The SREBP-mediated pathway begins in the membranes of the endoplasmic reticulum (ER) and includes at least two other proteins besides SREBP.

When cells have adequate concentrations of cholesterol, SREBP is found in the ER membrane complexed with SCAP (SREBP cleavage-activating protein), *insig-1* (or its close homolog *insig-2*), and perhaps other proteins (Figure 16-37a). SREBP has three distinct domains: an N-terminal cytosolic domain, containing a basic helix-loop-helix (bHLH) DNA-binding motif (see Figure 7-29) that functions as a transcription factor when cleaved from the rest of SREBP; a central membrane-anchoring domain containing two transmembrane α helices; and a C-terminal cytosolic regulatory domain. SCAP has eight transmembrane α helices and a large C-terminal cytosolic domain that interacts with the regulatory domain of SREBP. Five of the transmembrane α helices in SCAP form a *sterol-sensing domain* similar to that in HMG-CoA reductase (Figure 16-37a; see Section 10.3). When

FIGURE 16-37 Cholesterol-sensitive control of SREBP activation.

The cellular pool of cholesterol is monitored by the combined action of *insig-1*(2) and SCAP, both transmembrane proteins located in the ER membrane. Membrane-spanning helices 2-6 of SCAP (orange with black lines) form a sterol-binding domain, and a C-terminal segment binds to SREBP. (a) When cholesterol levels are high such that ER cholesterol exceeds 5 percent of total ER lipids, cholesterol binds to the sterol-sensing domain in SCAP, triggering a conformational change that enables the N-terminal SCAP domain to bind to *insig-1*(2), anchoring the SCAP-SREBP complex in the ER membrane. (b) At low cholesterol levels, cholesterol dissociates from the SCAP sterol-sensing

domain, triggering a reverse conformational change that dissociates SCAP from *insig-1*(2) and enables SCAP to bind to Sec24, a subunit of the COPII complex (see Figure 14-8). This initiates movement of the SCAP-SREBP complex to the Golgi complex by vesicular transport. In the Golgi, the sequential cleavage of SREBP by the site 1 and site 2 proteases (S1P, S2P) releases the N-terminal bHLH domain of SREBP. After this released domain, called nuclear SREBP (nSREBP), translocates into the nucleus, it controls the transcription of genes containing sterol regulatory elements (SREs) in their promoters. [Adapted from A. Radhakrishnan, 2008, *Cell Metab.* **8**:451, and M. Brown and J. Goldstein, 2009, *J. Lipid. Res.* **50**:S15.]

the sterol-sensing domain in SCAP is bound to cholesterol, the protein also binds to insig-1(2). When insig-1(2) is tightly bound to the SCAP-cholesterol complex, it blocks the binding of SCAP to the Sec24 coat protein subunit of COPII vesicles, thereby preventing incorporation of the SCAP-SREBP complex into ER-to-Golgi transport vesicles (see Chapter 14). This occurs when cholesterol concentrations in the ER membrane exceed 5 percent of total ER membrane lipids. Thus the cholesterol-dependent binding of insig to the SCAP-cholesterol-SREBP complex traps that complex in the ER.

Cholesterol bound to SCAP is released when cellular cholesterol levels drop to less than 5 percent of ER lipids, a value that reflects total cellular cholesterol levels. Consequently, insig-1(2) no longer binds to the cholesterol-free SCAP, and the SCAP-SREBP complex moves from the ER to the Golgi apparatus via COPII vesicles (Figure 16-37b). In the Golgi, SREBP is cleaved sequentially at two sites by two membrane-bound proteases, S1P and S2P; the latter is an additional example of regulated intramembrane proteolysis. The second cleavage at site 2 releases the N-terminal bHLH-containing domain into the cytosol. This fragment, called *nSREBP* (*nuclear SREBP*), is rapidly translocated into the nucleus. There it activates transcription of genes containing *sterol regulatory elements* (SREs) in their promoters, such as those encoding the LDL receptor and HMG-CoA reductase. Thus a reduction in cellular cholesterol, by activating the *insig1(2)/SCAP/SREBP pathway*, triggers expression of genes encoding proteins that both import cholesterol into the cell (the LDL receptor) and synthesize cholesterol from small precursor molecules (HMG-CoA reductase).

After cleavage of SREBP in the Golgi, SCAP apparently recycles back to the ER, where it can interact with insig-1(2) and another intact SREBP molecule. High-level transcription of SRE-controlled genes requires the ongoing generation of new *nSREBP* because it is degraded fairly rapidly by the ubiquitin-mediated proteasomal pathway (see Chapter 3). The rapid generation and degradation of *nSREBP* help cells respond quickly to changes in levels of intracellular cholesterol.

Under some circumstances (e.g., during cell growth), cells need an increased supply of all the essential membrane lipids and their fatty acid precursors (coordinate regulation). But cells sometimes need greater amounts of some lipids, such as cholesterol, to make steroid hormones, than others, such as phospholipids (differential regulation). How is such differential production achieved? Mammals express three known isoforms of SREBP: SREBP-1a and SREBP-1c, which are generated from alternatively spliced RNAs produced from the same gene, and SREBP-2, which is encoded by a different gene. Together, these RIP-regulated transcription factors control expression of proteins that regulate availability not only of cholesterol but also of fatty acids and the triglycerides and phospholipids made from fatty acids. In mammalian cells, SREBP-1a and SREBP-1c exert a greater influence on fatty acid metabolism than on cholesterol metabolism, whereas the reverse is the case for SREBP-2.

Because the risk for atherosclerotic disease, the major cause of heart attacks, is directly proportional to the plasma levels of LDL cholesterol (the so-called bad cholesterol) and inversely proportional to those of HDL cholesterol, a major public health goal has been to lower LDL and raise HDL cholesterol levels. The most successful drugs for controlling the LDL:HDL ratio are the statins, which cause reductions in plasma LDL. As discussed in Chapter 10, these drugs bind to HMG-CoA reductase and directly inhibit its activity, thereby lowering cholesterol biosynthesis and the pool of cholesterol in the liver. Activation of SREBP in response to this cholesterol depletion promotes increased synthesis of HMG-CoA reductase and the LDL receptor. Of greatest importance here is the resulting increased numbers of hepatic LDL receptors, which mediate increased import of LDL cholesterol from the blood and so lower the level of LDL cholesterol in the circulation. Thus statins may inhibit atherosclerosis and heart disease by mechanisms independent of their inhibition of cholesterol biosynthesis, but these mechanisms are not well understood. ■

KEY CONCEPTS of Section 16.6

Signaling Pathways Controlled by Protein Cleavage: Notch/Delta, SREBP

- Many important growth factors and other signaling proteins such as EGFs are synthesized as transmembrane proteins; regulated cleavage of the precursor near the plasma membrane by members of the matrix metalloprotease (MMP) family releases the active molecule into the extracellular space to signal distant cells.
- On binding to its ligand Delta on the surface of an adjacent cell, the receptor Notch protein undergoes two proteolytic cleavages (see Figure 16-35). The released Notch cytosolic segment then translocates into the nucleus and modulates transcription of target genes critical in determining cell fate during development.
- Cleavage of membrane-bound precursors of members of the EGF family of signaling molecules is catalyzed by ADAM metalloproteases. Inappropriate cleavage of these precursors can result in abnormal cell proliferation, potentially leading to cancer, cardiac hypertrophy, and other diseases.
- γ -Secretase, which catalyzes the regulated intramembrane proteolysis of Notch, also participates in the cleavage of amyloid precursor protein (APP) into a peptide that forms plaques characteristic of Alzheimer's disease (see Figure 16-36).
- In the *insig-1(2)/SCAP/SREBP pathway*, the active *nSREBP* transcription factor is released from the Golgi membrane by intramembrane proteolysis when cellular cholesterol is low (see Figure 16-37). It then stimulates the expression of genes encoding proteins that function in cholesterol biosynthesis (e.g., HMG-CoA reductase) and cellular import of cholesterol (e.g., LDL receptor). When cholesterol is high, SREBP is retained in the ER membrane complexed with insig-1(2) and SCAP.

16.7 Integration of Cellular Responses to Multiple Signaling Pathways

In this section, we consider how multiple signal transduction pathways interact. We will focus on only one of the myriad of systems controlled by multiple signaling pathways—regulation of the body's needs for the metabolites glucose and fatty acids. We'll first consider several key cellular responses to variations in the demand for the key metabolite glucose. Then we'll turn to control of production of the one type of cell in the adult body that can increase in mass and number almost without limit—the adipose, or fat-storing cell. Cellular responses to changes in other nutrients and to oxygen, which are largely reflected in alterations in gene expression, are covered in Chapter 7.

Insulin and Glucagon Work Together to Maintain a Stable Blood Glucose Level

During normal daily living, the maintenance of normal blood glucose concentrations depends on the balance between two peptide hormones, **insulin** and **glucagon**, which are made in distinct pancreatic islet cells and elicit different cellular responses. Insulin, which contains two polypeptide chains linked by disulfide bonds, is synthesized by the β cells in the islets (see Figures 14-23 and 14-24); glucagon, a monomeric peptide, is produced by the α islet cells. Insulin *reduces* the level of blood glucose, whereas glucagon *increases* blood glucose. The availability of blood glucose is regulated during periods of abundance (following a meal) or scarcity (following fasting) by the adjustment of insulin and glucagon concentrations in the blood.

After a meal, when blood glucose rises above its normal level of 5 mM, the pancreatic β cells respond to the rise in glucose (and amino acids) by releasing insulin into the blood (Figure 16-38). The released insulin circulates in the blood and binds to insulin receptors present on many different kinds of cells, including muscle and adipocyte cells. The insulin receptor, a receptor tyrosine kinase, activates several signal transduction pathways, including the one leading to the activation of protein kinase B (PKB; see Figure 16-26). In this case, the main actions of these signaling pathways are manifest within minutes. The active PKB phosphorylates a specific target protein that then triggers the rapid fusion of intracellular vesicles containing the glucose transporter GLUT4 with the plasma membrane (Figure 16-39). The resulting immediate tenfold increase in the number of GLUT4 molecules on the cell surface increases glucose influx proportionally, thus lowering blood glucose.

Insulin stimulation of muscle cells enhances within minutes the conversion of glucose into glycogen, and PKB, activated downstream of the insulin receptor, again plays a crucial role. Active PKB phosphorylates glycogen synthase kinase 3 (GSK3, the same enzyme that functions in the Wnt and Hh pathways). Although GSK in non-insulin-stimulated cells can phosphorylate glycogen synthase and thus inhibit

FIGURE 16-38 Secretion of insulin in response to a rise in blood glucose. The entry of glucose into pancreatic β cells is mediated by the GLUT2 glucose transporter (1). Because the K_m for glucose of GLUT2 is ~ 20 mM, a rise in extracellular glucose from 5 mM, characteristic of the fasting state, causes a proportionate increase in the rate of glucose entry (see Figure 11-4). The conversion of glucose into pyruvate is thus accelerated, resulting in an increase in the concentration of ATP in the cytosol (2). The binding of ATP to ATP-sensitive K^+ channels closes these channels (3), thus reducing the efflux of K^+ ions from the cell. The resulting small depolarization of the plasma membrane (4) triggers the opening of voltage-sensitive Ca^{2+} channels (5). The influx of Ca^{2+} ions raises the cytosolic Ca^{2+} concentration, triggering the fusion of insulin-containing secretory vesicles with the plasma membrane and the secretion of insulin (6). [Adapted from J. Q. Henquin, 2000, *Diabetes* 49:1751.]

its activity, in insulin-treated muscle, GSK3 phosphorylated by PKB cannot phosphorylate glycogen synthase; thus insulin-stimulated activation of PKB results in net short-term activation of glycogen synthase and glycogen synthesis. Insulin also acts on hepatocytes (liver cells) to inhibit glucose synthesis from smaller molecules, such as lactate and acetate, and to enhance glycogen synthesis from glucose. Many of these effects are manifest at the level of gene transcription since insulin signaling reduces expression of genes whose encoded enzymes stimulate synthesis of glucose from small metabolites such as pyruvic acid. The net effect of all these actions is to lower blood glucose back to the fasting concentration of about 5 mM while storing the excess glucose intracellularly as glycogen for future use.

As the blood glucose level drops, insulin secretion and blood levels drop, and insulin receptors are no longer being activated as strongly. In muscles, the response is that cell-surface GLUT4 becomes internalized by endocytosis, lowering the level of cell-surface GLUT4 and thus glucose import. If the blood glucose level falls below about 5 mM, for example due to sudden muscular activity, reduced insulin secretion

EXPERIMENTAL FIGURE 16-39 Insulin stimulation of fat cells induces translocation of GLUT4 from intracellular vesicles to the plasma membrane. (a) Outline of the experiment: Cultured adipose cells were engineered to express a chimeric protein whose N-terminal end corresponded to the GLUT4 sequence, followed by the entirety of the GFP sequence; inserted into the GLUT4 extracellular loop between helices 1 and 2 is a "myc" epitope that is recognized by a red-fluorescing anti-epitope monoclonal antibody added to the outside of the cell. Thus green fluorescence monitors the total cellular GLUT4 while red fluorescence measures only cell surface GLUT4. (b) Cultured adipocytes expressing this recombinant GLUT4 protein were untreated (*top*) or

treated with insulin (*bottom*), reacted with the red-fluorescing anti-epitope antibody, then fixed and viewed under a confocal fluorescence microscope. In the absence of insulin, virtually all of the GLUT4 is in intracellular membranes that are not connected to the plasma membrane; there is little surface staining. Insulin triggers fusion of the GLUT4-containing membranes with the plasma membrane, thereby moving GLUT4 to the cell surface and enabling it to transport glucose from the blood into the cell. Muscle cells also contain insulin-responsive GLUT4 transporters. Arrows highlight GLUT4 present at the plasma membrane; *N* indicates the position of the nuclei. [Courtesy of J. Bogan; see C. Yu et al., 2007, *J. Biol. Chem.* **282**:7710.]

from pancreatic β cells induces pancreatic α cells to increase their secretion of glucagon into the blood. Like the epinephrine receptor, the glucagon receptor, found primarily on liver cells, is coupled to the $G_{\alpha s}$ protein, whose effector protein is adenylyl cyclase. Glucagon stimulation of liver cells induces a rise in cAMP, leading to activation of protein kinase A, which inhibits glycogen synthesis and promotes

glycogenolysis, yielding glucose 1-phosphate (see Figures 15-31a and 15-38b). Liver cells convert glucose 1-phosphate into glucose, which is released into the blood, thus raising blood glucose back toward its normal fasting level.

Unfortunately, these intricate and powerful control systems sometimes fail, causing serious, even life-threatening

disease. *Diabetes mellitus* results from a deficiency in the amount of insulin released from the pancreas in response to rising blood glucose (type I) or from a decrease in the ability of muscle and fat cells to respond to insulin (type II). In both types, the regulation of blood glucose is impaired, leading to persistent elevated blood glucose concentrations (hyperglycemia) and other possible complications if left untreated. Type I diabetes is caused by an autoimmune process that destroys the insulin-producing β cells in the pancreas. Also called insulin-dependent diabetes, this form of the disease is generally responsive to insulin therapy. Most Americans with diabetes mellitus have type II, or insulin-independent diabetes. While the underlying cause of this form of the disease is not well understood, obesity is correlated with a huge increase in the incidence of diabetes. Further identification of the signaling pathways that control energy metabolism is expected to provide insight into the pathophysiology of diabetes, hopefully leading to new methods for its prevention and treatment. ■

Multiple Signal Transduction Pathways Interact to Regulate Adipocyte Differentiation Through PPAR γ , the Master Transcriptional Regulator

White adipocytes, commonly called “fat cells,” are the major depots for storage of fats; mature adipocytes have a few triglyceride globules that occupy the bulk of the cell. Adipocytes are also endocrine cells and secrete several signaling proteins that affect the metabolic functions of muscle, liver, and other organs. Adipocytes are the one type of cell in the body that can increase both in number and size almost without limit. Readers in every country do not need to be reminded that obesity—an overabundance of adipocytes—is a growing public health problem, and obesity is a major risk factor not only for diabetes but also for cardiovascular diseases such as heart attacks and stroke and certain cancers. Thus much effort has gone into understanding the factors that regulate fat-cell formation, with the hope of developing drugs that can slow or reverse the process.

As we discuss in Chapter 21, several types of stem cells reside in vertebrates and are used to generate specific types of differentiated cells. The **mesenchymal stem cell** resides in the bone marrow and other organs and gives rise to progenitor cells that in turn can form either adipocytes, cartilage-producing cells, or bone-forming osteoblasts. The adipocyte progenitor, called the preadipocyte, has lost the potential to differentiate into other cell types. When treated with specific hormones, preadipocytes undergo terminal differentiation; they acquire the proteins that are necessary for lipid transport and synthesis, insulin responsiveness, and the secretion of adipocyte-specific proteins. Several lines of cultured preadipocytes can differentiate into adipocytes and express adipocyte-specific mRNAs and proteins, such as enzymes required for triglyceride synthesis.

The transcription factor PPAR γ , a member of the nuclear-receptor superfamily, is the master transcriptional regulator

of adipocyte differentiation. As evidence, recombinant expression of PPAR γ in many fibroblast lines is sufficient to trigger their differentiation into adipocytes. Conversely, knocking down the gene for PPAR γ in preadipocytes totally prevents their differentiation into adipocytes. Most hormones such as insulin that promote adipogenesis do so at least in part by activating expression of PPAR γ . PPAR γ , in turn, binds to the promoters of most adipocyte-specific genes and induces their expression, including genes encoding proteins needed in the insulin-signaling pathway such as the insulin receptor and GLUT4. Like other members of the nuclear-receptor superfamily, such as steroid hormone receptors (see Chapter 7), which become activated when they bind their ligand, PPAR γ is also thought to bind a ligand, probably an oxidized derivative of a fatty acid.

Another transcription factor, C/EBP α , is induced during adipocyte differentiation and also directly induces many adipocyte genes. Importantly, C/EBP α induces expression of the PPAR γ gene and PPAR γ induces expression of C/EBP α , leading to a rapid increase in both proteins during the first two days of differentiation. PPAR γ together with C/EBP α induces expression of all genes required for differentiation of preadipocytes into mature fat cells.

Many signaling proteins such as Wnt and TGF- β oppose the action of insulin and prevent preadipocyte differentiation into adipocytes. As Figure 16-40 shows, transcription factors activated by receptors for these hormones prevent expression of the PPAR γ gene, in part by blocking the ability of C/EBP α to induce PPAR γ gene expression. Thus multiple extracellular signals act in concert to regulate adipogenesis, and the signal transduction pathways activated by them intersect at the regulation of expression of one key “master” gene, encoding PPAR γ .

KEY CONCEPTS of Section 16.7

Integration of Cellular Responses to Multiple Signaling Pathways

- A rise in blood glucose stimulates the release of insulin from pancreatic β cells (see Figure 16-38). Subsequent binding of insulin to its receptor on muscle cells and adipocytes leads to the activation of protein kinase B, which promotes glucose uptake and glycogen synthesis, resulting in a decrease in blood glucose (see Figure 16-39).
- A lowering of blood glucose stimulates glucagon release from pancreatic α cells. Binding of glucagon to its G protein-coupled receptor on liver cells promotes glycogenolysis by the cAMP-triggered kinase cascade (similar to epinephrine stimulation under stress conditions) and an increase in blood glucose (see Figures 15-31a and 15-38b).
- PPAR γ , a member of the nuclear receptor superfamily, is the master transcriptional regulator of adipocyte differentiation.

FIGURE 16-40 Multiple signal transduction pathways interact to regulate adipocyte differentiation. The transcription factor PPAR γ (purple oval) is the master regulator of adipocyte differentiation; together with C/EBP α , it induces expression of all genes required for differentiation of preadipocytes into mature fat cells. Both PPAR γ and C/EBP α are induced early in adipogenesis; each of them enhances the transcription of the other's gene (an arrow at the end of a line means enhancement of expression of target genes), leading to a rapid increase in expression of both proteins during the first two days of differentiation. Signals from hormones such as insulin and growth factors such as Wnt and TGF- β that activate or repress adipogenesis are integrated in the nucleus by transcription factors that regulate—directly or indirectly—expression of the PPAR γ and C/EBP α genes. A T at the end of a line indicates inhibition of expression of the target gene. (a) Insulin activates adipogenesis by several pathways leading to activation of PPAR γ expression, two of which are depicted here. Activation of protein kinase B (PKB) downstream of the IGF1 receptor tyrosine kinase

and IRS1 leads to repression of Necdin expression; Necdin, by modulating other transcription factors, would otherwise repress expression of the PPAR γ gene. PKB also phosphorylates and thus inactivates the transcription factor GATA2, which when unphosphorylated binds to the C/EBP α protein and prevents it from activating expression of the PPAR γ gene. By inhibiting two repressors of the PPAR γ gene, insulin thus stimulates PPAR γ expression. (b) Wnt and TGF- β inhibit adipogenesis by reducing expression of the PPAR γ gene. Wnt signaling triggers release of β -catenin from a cytoplasmic complex, and free β -catenin binds the transcription factor TCF (see Figure 16-30). Active TCF blocks expression of the PPAR γ and C/EBP α genes, probably by binding to their regulatory sequences. (c) Smad3, activated by phosphorylation following TGF- β binding to the types I and II TGF- β receptors, binds to the C/EBP α protein and prevents it from activating expression of the PPAR γ gene. [After E. Rosen and O. MacDougald, 2006, *Nature Rev. Mol. Cell Biol.* 7:885.]

- Extracellular hormones such as insulin that promote adipocyte differentiation induce signal transduction pathways that lead to enhanced production of PPAR γ . Conversely, signaling proteins such as Wnt and TGF- β that prevent preadipocyte differentiation activate signaling pathways that prevent expression of the PPAR γ gene (see Figure 16-40).

Perspectives for the Future

The confluence of genetics, biochemistry, and structural biology has given us an increasingly detailed view of how signals are transmitted from the cell surface and transduced into changes in cellular behavior. The multitude of different extracellular signals, receptors for them, and intracellular

signal transduction pathways fall into a relatively small number of classes, and one major goal is to understand how similar signaling pathways often regulate very different cellular processes. For instance, STAT5 activates very different sets of genes in erythroid precursor cells, following stimulation of the erythropoietin receptor, than in mammary epithelial cells, following stimulation of the prolactin receptor. Presumably STAT5 binds to different groups of transcription factors in these and other cell types, but the nature of these proteins and how they collaborate to induce cell-specific patterns of gene expression remain to be uncovered.

Conversely, activation of the same signal transduction component in the same cell through different receptors often elicits different cellular responses. One commonly held view is that the duration of activation of the MAP kinase and other signaling pathways affects the pattern of gene expression. But how this specificity is determined remains an outstanding question in signal transduction. Genetic and molecular studies in flies, worms, and mice will contribute to our understanding of the interplay between different pathway components and the underlying regulatory principles controlling specificity in multicellular organisms.

Researchers have determined the three-dimensional structures of various signaling proteins during the past several years, permitting more detailed analysis of several signal transduction pathways. The molecular structures of different kinases, for example, exhibit striking similarities and important variations that impart to them novel regulatory features. The activity of several kinases, such as Raf and protein kinase B (PKB), is controlled by inhibitory domains as well as by multiple phosphorylations catalyzed by several other kinases. Our understanding of how the activity of these and other kinases is precisely regulated to meet the cell's needs will require additional structural and cell biological studies.

Abnormalities in signal transduction underlie many different diseases, including the majority of cancers and many inflammatory conditions. Detailed knowledge of the signaling pathways involved and the structure of their protein components will continue to provide important molecular clues for the design of specific therapies. Despite the close structural relationship between different signaling molecules (e.g., kinases), recent studies suggest that inhibitors selective for specific subclasses can be designed. In many tumors of epithelial origin, the EGF receptor has undergone a specific mutation that increases its activity. Remarkably a small-molecule drug (Iressa) inhibits the kinase activity of the mutant EGF receptor but has no effect on the normal EGF receptor or other receptors. Thus the drug slows cancer growth only in patients with this particular mutation. Similarly, monoclonal antibodies or decoy receptors (soluble proteins that contain the ligand-binding domain of a receptor and so sequester the ligand) that prevent pro-inflammatory cytokines such as IL-1 and TNF- α from binding to their cognate receptors are now being used in treatment of several inflammatory diseases such as arthritis.

Key Terms

activation lip 724	PI-3 kinase pathway 745
adapter protein 737	PPAR γ 767
constitutive 749	presenilin 1 761
cytokines 721	primary cilium 756
diabetes mellitus 767	protein kinase B (PKB) 746
erythropoietin (Epo) 728	PTB (phosphotyrosine-binding) domain 730
Hedgehog (Hh) pathway 753	PTEN phosphatase 747
HER family 726	Ras protein 734
insig-1(2)/SCAP/SREBP pathway 764	receptor tyrosine kinases (RTKs) 723
insulin 765	regulated intramembrane proteolysis (RIP) 761
JAK/STAT pathway 734	scaffold proteins 744
kinase cascade 735	SH2 domains 730
MAP kinase 735	Smads 749
matrix metalloprotease (MMP) family 760	SRE-binding protein (SREBP) 763
NF- κ B pathway 752	transforming growth factor β (TGF- β) 748
Notch/Delta pathway 760	Wnt pathway 752
nuclear-localization signal (NLS) 749	
phosphoinositides 745	

Review the Concepts

1. Name three features common to the activation of cytokine receptors and receptor tyrosine kinases. Name one difference with respect to the enzymatic activity of these receptors.
2. Erythropoietin (Epo) is a hormone that is produced naturally in the body in response to low O₂ levels in the blood. The intracellular events that occur in response to Epo binding to its cell-surface receptor are well characterized. What molecule translocates from the cytosol to the nucleus after (a) JAK2 activates STAT5 and (b) GRB2 binds to the Epo receptor? Why did some endurance athletes use Epo to improve their performance ("blood doping") until it was banned by most sports?
3. Explain how expression of a dominant-negative mutant of JAK blocks the erythropoietin (Epo)-cytokine signaling pathway.
4. Even though GRB2 lacks intrinsic enzymatic activity, it is an essential component of the epidermal growth factor (EGF) signaling pathway that activates MAP kinase. What is the function of GRB2? What role do the SH2 and SH3 domains play in the function of GRB2? Many other signaling proteins possess SH2 domains. What determines the specificity of SH2 interactions with other molecules?
5. Once an activated signaling pathway has elicited the proper changes in target gene expression, the pathway must be inactivated. Otherwise, pathologic consequences may result, as exemplified by persistent growth factor-initiated signaling in many cancers. Many signaling pathways possess

intrinsic negative feedback by which a downstream event in a pathway turns off an upstream event. Describe the negative feedback that down-regulates signals induced by (a) erythropoietin and (b) TGF- β .

6. A mutation in the Ras protein renders Ras constitutively active (Ras^D). What is constitutive activation? How is constitutively active Ras cancer promoting? What type of mutation might render the following proteins constitutively active: (a) Smad3, (b) MAP kinase, and (c) NF- κ B?

7. The enzyme Ste11 participates in several distinct MAP kinase signaling pathways in the budding yeast *S. cerevisiae*. What is the substrate for Ste11 in the mating factor signaling pathway? When a yeast cell is stimulated by mating factor, what prevents induction of osmolytes required for survival in high-osmotic-strength media since Ste11 also participates in the MAP kinase pathway initiated by high osmolarity?

8. Describe the events required for full activation of protein kinase B. Name two effects of insulin mediated by protein kinase B in muscle cells.

9. Describe the function of the PTEN phosphatase in the PI-3 kinase signaling pathway. Why is a loss-of-function mutation in PTEN cancer promoting? Predict the effect of constitutively active PTEN on cell growth and survival.

10. Binding of TGF- β to its receptors can elicit a variety of responses in different cell types. For example, TGF- β induces plasminogen activator inhibitor in epithelial cells and specific immunoglobulins in B cells. In both cell types, Smad3 is activated. Given the conservation of the signaling pathway, what accounts for the diversity of the response to TGF- β in various cell types?

11. How is the signal generated by binding of TGF- β to cell-surface receptors transmitted to the nucleus, where changes in target gene expression occur? What activity in the nucleus ensures that the concentration of active Smads closely reflects the level of activated TGF- β receptors on the cell surface?

12. The extracellular signaling protein Hedgehog can remain anchored to cell membranes. What modifications to Hedgehog enable it to be membrane bound? Why is this property useful?

13. Explain why loss-of-function *hedgehog* and *smoothened* mutations yield the same phenotype but a loss-of-function *patched* mutation yields the opposite phenotype in flies.

14. Most mammalian cells have a single immobile cilium called the primary cilium, in which intraflagellar transport (IFT) microtubule motor proteins (discussed in greater detail in Chapter 18) move elements of the Hedgehog (Hh) signaling pathway. What parts of the Hh signaling pathway would mutations in the IFT motor proteins Kif3A, Kif7, and dynein disrupt?

15. Why is the signaling pathway that activates NF- κ B considered to be relatively irreversible compared with cytokine or RTK signaling pathways? Nonetheless, NF- κ B signaling must be down-regulated eventually. How is the NF- κ B signaling pathway turned off?

16. Describe two roles for polyubiquitination in the NF- κ B signaling pathway.

17. What feature of Delta ensures that only neighboring cells are signaled?

18. What biochemical reaction is catalyzed by γ -secretase? Why was it proposed that a chemical inhibitor of this activity might be a useful drug for treating Alzheimer's disease? What possible side effects of such a drug would complicate this use?

Analyze the Data

1. G. Johnson and colleagues have analyzed the MAP kinase cascade in which MEKK2 participates in mammalian cells. By a yeast two-hybrid screen (see Chapter 7), MEKK2 was found to bind MEK5, which can phosphorylate a MAP kinase. To elucidate the signaling pathway transduced by MEKK2 in vivo, the following studies were performed in human embryonic kidney (HEK293) cells in culture.

a. HEK293 cells were transfected with a plasmid encoding recombinant, tagged MEKK2, along with a plasmid encoding MEK5 or a control vector that did not encode a protein (mock). Recombinant MEK5 was precipitated from the cell extract by absorption to a specific antibody. The immunoprecipitated material was then resolved by polyacrylamide gel electrophoresis, transferred to a membrane, and examined by Western blotting with an antibody that recognized tagged MEKK2. The results are shown in part (a) of the figure below. What information about this MAP kinase cascade do we learn from this experiment? Do the data in part (a) of the figure prove that MEKK2 activates MEK5 or vice versa?

b. ERK5 is a MAP kinase previously shown to be activated when phosphorylated by MEK5. When ERK5 is phosphorylated by MEK5, its migration on a polyacrylamide gel is retarded. In another experiment, HEK293 cells were transfected with a plasmid encoding ERK5 along with plasmids encoding MEK5, MEKK2, MEKK2, and MEK5 or MEKK2 and MEK5AA. MEK5AA is a mutant, inactive version of MEK5 that functions as a dominant-negative. Expression of MEK5AA in HEK293 cells prevents signaling through active, endogenous MEK5. Lysates of transfected cells were analyzed by Western blotting with an antibody against recombinant ERK5. From the data in part (b) of the figure, what can we conclude about the role of MEKK2 in the activation of ERK5? How do the data obtained when cells are cotransfected with ERK5, MEKK2, and MEK5AA help to elucidate the order of participants in this kinase cascade?

2. Scaffold proteins can segregate different MAPK signaling pathways that share common components. In the yeast mating pathway, the MEK (MAPKK) Ste7 phosphorylates and activates the Fus3 MAPK, whereas Ste7 phosphorylates and activates the Kss1 MAPK in the starvation pathway. The mating pathway is activated by mating factor receptor activation of a G-protein; $G_{\beta\gamma}$ recruits the Ste5 scaffold protein and the Ste11, Ste7, and Fus3 components of the kinase cascade. Mutation of the Ste5 binding sites for Ste11 and Ste7 disrupts the mating response, clearly demonstrating the importance of Ste5 for tethering the kinases together. Mutation of the Fus3 binding site on Ste5 gave a more complicated response, suggesting that Ste5-Fus3 interaction may involve more than just tethering. This possibility was investigated with yeast proteins expressed as recombinant proteins in bacteria or insect cells and then purified (see Good et al., 2009, *Cell* 136:1085–1097).

a. A fluorescence quenching assay was used to measure the activity of Fus3 and Kss1 MAP kinases using a substrate peptide that can be phosphorylated by both kinases. Phosphorylated peptide binds to gallium coupled to fluorescence

beads and quenches the fluorescence. The rate of fluorescence quenching (loss of fluorescence) corresponds to the Fus3 or Kss1 kinase activity. Results of Ste7 phosphorylation and thereby activation of Kss1 and Fus3 in the presence and absence of Ste5 are shown below:

Quenching curves:

1. Fus3 or Kss1 alone (control)
2. Fus3 or Kss1 + Ste7
3. Fus3 or Kss1 + Ste7 + Ste5

Is Ste5 required for Ste7 activity? Does Ste7 activate Fus3 and Kss1 equivalently? What does the effect of the presence or absence of Ste5 in the assay tell you about Ste7 phosphorylation and activation of Fus3 and Kss1?

b. The protein sequences of Fus3 and Kss1 are 55 percent identical, but each has a unique so-called MAPK insertion loop near the activation domain that is phosphorylated by Ste7. Mutation of an isoleucine residue in the Fus3 insertion loop or replacement of the Fus3 insertion loop with the equivalent region of Kss1 both yield curves similar to Kss1 curve 2. What does this suggest about Fus3 and Kss1 as substrates for Ste7 and the role of Ste5 in stimulating Ste7 phosphorylation of Fus3?

A section of mouse intestine stained for actin (red), the extracellular matrix protein laminin (green), and DNA (blue). Each blue dot of DNA indicates the presence of a cell. Actin in the microvilli on the apical end of the epithelial cells can be seen lining the surface facing the lumen (*top*). Actin can also be seen prominently in the smooth muscle that surrounds the intestine (*bottom*). [Micrograph courtesy of Thomas Deerinck and Mark Ellisman.]

Cell Organization and Movement I: Microfilaments

When we look through a microscope at the wonderful diversity of cells in nature, the variety of cell shapes and movements we can discern is astonishing. At first we may notice that some cells, such as vertebrate sperm, ciliates such as *Tetrahymena*, or flagellates such as *Chlamydomonas*, swim rapidly, propelled by cilia and flagella. Other cells, such as amoebas and human macrophages, move more sedately, propelled not by external appendages but by coordinated movement of the cell itself. We also might notice that some cells in tissues attach to one another, forming a pavementlike sheet, whereas other cells—neurons, for example—have long processes, up to 3 ft in length, and make selective contacts between cells. Looking more closely at the internal organization of cells, we see that organelles have characteristic locations; for example, the Golgi apparatus is generally near the central nucleus. How is this diversity of shape, cellular organization, and motility achieved? Why is it important for cells to have a distinct shape and clear internal organization? Let us first consider two examples of cells with very different functions and organizations.

The epithelial cells that line the intestine form a tight, pavementlike layer of brick-shaped cells, known as an epithelium

(Figure 17-1a, b). Their function is to import nutrients (such as glucose) from the intestinal lumen across the apical (top) plasma membrane and export them across the basolateral (bottom-side) plasma membrane toward the bloodstream. To perform this directional transport, the apical and basolateral plasma membranes of epithelial cells must have different protein compositions. Epithelial cells are attached and sealed together by cellular junctions (discussed in Chapter 20), which create a physical barrier between the apical and basolateral domains of the membrane. This separation allows the cell to place the correct transport proteins in the plasma membranes of the two surfaces. In addition, the apical membrane has a unique morphology, with numerous fingerlike projections called **microvilli** that increase the area of the plasma membrane available for nutrient absorption. To achieve this organization, epithelial cells must have an internal structure to give them shape and to deliver the appropriate proteins to the correct membrane surface.

Now consider macrophages, a type of white blood cell that seeks out infectious agents and destroys them by an engulfing process called phagocytosis. Bacteria release chemicals that attract the macrophage and guide it to the infection.

FIGURE 17-1 Overview of the cytoskeletons of an epithelial cell and a migrating cell. (a) Transmission electron micrograph of a thin section of an epithelial cell from the small intestine, showing the cytoskeletal components of the microvilli. (b) Epithelial cells are highly polarized, with distinct apical and basolateral domains. An intestinal epithelial cell transports nutrients into the cell through the apical domain and out of the cell across the basolateral domain. (c) Transmission electron micrograph of part of the leading edge of a migrating cell. The cell was treated with a mild detergent to dissolve the membranes, which

also allows solubilization of most cytoplasmic components. The remaining cytoskeleton was shadowed with platinum and visualized in the electron microscope. Note the meshwork of actin filaments visible in this micrograph. (d) A migrating cell, such as a fibroblast or a macrophage, has morphologically distinct domains, with a leading edge at the front. Microfilaments are indicated in red, microtubules in green, and intermediate filaments in dark blue. The position of the nucleus (light blue oval) is also shown. As the macrophage follows the chemical gradient, twisting and turning to get to the bacteria and phagocytose them, it has to constantly reorganize its cell locomotion machinery. As we will see, the internal motile machinery of macrophages and other crawling cells is always oriented in the direction that they crawl (Figure 17-1c, d).

These are just two examples of cell polarity—the ability of cells to generate functionally distinct regions. In fact, as you think about all types of cells, you will realize that most of them have some form of cell polarity. An additional and fundamental example of cell polarity is the ability of cells to divide: they must first select an axis for cell division and

then set up the machinery to segregate their organelles along that axis.

A cell's shape, internal organization, and functional polarity are provided by a three-dimensional filamentous protein network called the **cytoskeleton**. The cytoskeleton can be isolated and visualized after treating cells with gentle detergents that solubilize the plasma membrane and internal organelles, releasing most of the cytoplasm (Figure 17-1c). The cytoskeleton extends throughout the cell and is attached to the plasma membrane and internal organelles, thus providing a framework for cellular organization. The term *cytoskeleton* may imply a fixed structure like a bone skeleton. In

FIGURE 17-2 The components of the cytoskeleton. Each filament type is assembled from specific subunits in a reversible process so that cells can assemble and disassemble filaments as needed. Bottom panels show localization of the three filament systems in cultured cells

as seen by immunofluorescence microscopy of actin, tubulin, and an intermediate filament protein, respectively. [Actin and tubulin courtesy of D. Garbett and A. Bretscher; intermediate filaments Copyright Molecular Expressions, Nikon & FSU.]

fact, the cytoskeleton can be very dynamic, with components capable of reorganization in less than a minute, or it can be quite stable for hours at a time. As a result, the lengths and dynamics of filaments can vary greatly, filaments can be assembled into diverse types of structures, and they can be regulated locally in the cell.

The cytoskeleton is composed of three major filament systems, shown in Figure 17-1b, d as well as in Figure 17-2, all of which are organized and regulated in time and space. Each filament system is composed of a polymer of assembled subunits. The subunits that make up the filaments undergo regulated assembly and disassembly, giving the cell the flexibility to assemble or disassemble different types of structures as needed.

- **Microfilaments** are polymers of the protein *actin* organized into functional bundles and networks by actin-binding proteins. Microfilaments are especially important in the organization of the plasma membrane, giving shape to surface structures such as microvilli. Microfilaments can function on their own or serve as tracks for ATP-powered myosin **motor proteins**, which provide a contractile function (as in muscle) or ferry cargo along microfilaments.

- **Microtubules** are long tubes formed by the protein *tubulin* and organized by microtubule-associated proteins. They often extend throughout the cell, providing an organizational framework for associated organelles and structural support to cilia and flagella. They also make up the structure of the mitotic spindle, the machine for separating duplicated chromosomes at mitosis. Molecular motors called kinesins and

dyneins transport cargo along microtubules and, like myosin, are also powered by ATP hydrolysis.

- **Intermediate filaments** are tissue-specific filamentous structures that serve a number of different functions, including lending structural support to the nuclear membrane, providing structural integrity to cells in tissues, and serving structural and barrier functions in skin, hair, and nails. Unlike the situation for microfilaments and microtubules, there are no motors that use intermediate filaments as tracks.

As we can see in Figure 17-1, cells can construct very different arrangements of their cytoskeletons. To establish these arrangements, cells must sense signals—either from soluble factors bathing the cell, from adjacent cells, or from the extracellular matrix—and interpret them (Figure 17-3). These signals are detected by cell-surface receptors that activate signal-transduction pathways that ultimately converge on factors that regulate cytoskeletal organization.

The importance of the cytoskeleton for normal cell function and motility is evident when a defect in a cytoskeletal component—or in cytoskeletal regulation—causes a disease. For example, about 1 in 500 people has a defect that affects the contractile apparatus of the heart, which results in cardiomyopathies varying in degree of severity. Many diseases of the red blood cell affect the cytoskeletal components that support these cells' plasma membranes. Metastatic cancer cells exhibit unregulated motility due to misregulation of the cytoskeleton, breaking away from their tissue of origin and migrating to new locations to form new colonies of uncontrolled growth.

FIGURE 17-3 Regulation of cytoskeleton function by cell signaling. Cells use cell-surface receptors to sense external signals from the extracellular matrix, other cells, or soluble factors. These signals are transmitted across the plasma membrane and activate specific cytosolic signaling pathways. Signals—often integrated from more than one receptor—lead to the organization of the cytoskeleton to provide cells with their shape, as well as to determine organelle distribution and movement. In the absence of external signals, cells still organize their internal structure, but not in a polarized manner.

In this and the following chapter, we discuss the structure, function, and regulation of the cytoskeleton. We will see how a cell arranges its cytoskeleton to determine cell shape and polarity, to provide organization and motility to its organelles, and to be the structural framework for such processes as cell swimming and cell crawling. We will discuss how cells assemble the three different filament systems and how signal-transduction pathways regulate these structures both locally and globally. How the cytoskeleton is regulated during the cell cycle is discussed in Chapter 19, and how it participates in the functional organization of tissue is covered in Chapter 20. Our focus in this chapter is on microfilaments and actin-based structures. Although we initially examine the cytoskeletal systems separately, in the next chapter we will see that microfilaments cooperate with microtubules and intermediate filaments in the normal functioning of cells.

17.1 Microfilaments and Actin Structures

Microfilaments can assemble into a wide variety of different types of structures within a cell (Figure 17-4a). Each of these diverse structures underlies particular cellular functions. Microfilaments can exist as a tight bundle of filaments making up the core of the slender, fingerlike *microvilli*, but they can also be found in a less ordered network beneath the plasma membrane, known as the *cell cortex*, where they provide support and organization. In epithelial cells, microfilaments

form a contractile band around the cell, the *adherens belt*, that is intimately associated with adherens junctions (Chapter 20) to provide strength to the epithelium. In migrating cells, a network of microfilaments is found at the front of the cell in the *leading edge*, or *lamellipodium*, which can also have protruding bundles of filaments called *filopodia*. Many cells have contractile microfilaments called *stress fibers*, which attach to the external substratum through specialized regions called *focal adhesions* or *focal contacts* (discussed in Chapter 20). Specialized cells such as macrophages use contractile microfilaments in a process called *phagocytosis* to engulf and internalize pathogens (such as bacteria), which are then destroyed internally. Highly dynamic, short bursts of actin filament assembly can power the movement of *endocytic vesicles* away from the plasma membrane. At a late stage of cell division in animals, after all the organelles have been duplicated and segregated, a *contractile ring* forms and constricts to generate two daughter cells in a process known as *cytokinesis*. Thus cells use actin filaments in many ways: in a structural role, by harnessing the power of actin polymerization to do work, or as tracks for myosin motors. The electron micrograph in Figure 17-4b shows microfilaments in microvilli. Different arrangements of microfilaments often coexist within a single cell, as shown in Figure 17-4c, in this case a migrating fibroblast.

The basic building block of microfilaments is **actin**, a protein that has the remarkable property of reversibly assembling into a polarized filament with functionally distinct ends. These filaments are then molded into the various structures described in the previous paragraph by actin-binding proteins. The name *microfilament* refers to actin in its polymerized form, with its associated proteins. In this section, we look at the actin protein itself and the filaments into which it assembles.

Actin Is Ancient, Abundant, and Highly Conserved

Actin is an abundant intracellular protein in eukaryotic cells. In muscle cells, for example, actin comprises 10 percent by weight of the total cell protein; even in nonmuscle cells, actin makes up 1–5 percent of the cellular protein. The cytosolic concentration of actin in nonmuscle cells ranges from 0.1 to 0.4 mM; in special structures such as microvilli, however, the local actin concentration can be as high as 5 mM. To grasp how much actin is present in cells, consider a typical liver cell, which has 2×10^4 insulin receptor molecules but approximately 5×10^8 , or half a billion, actin molecules. Because they form structures that extend across large parts of the cell interior, cytoskeletal proteins are among the most abundant proteins in a cell.

Actin is encoded by a large family of genes that gives rise to some of the most conserved proteins within and across species. The protein sequences of actins from amoebas and from animals are identical at 80 percent of the amino acid positions, despite about a billion years of evolution. The multiple actin genes found in modern eukaryotes are related

FIGURE 17-4 Examples of microfilament-based structures. (a) In each panel, microfilaments are depicted in red. (b) Scanning electron micrograph of the apical region of a polarized epithelial cell, showing the bundles of actin filaments that make up the cores of the microvilli.

(c) A cell moving toward the top of the page, stained for actin with fluorescent phalloidin, a drug that specifically binds F-actin. Note how many different organizations can exist in one cell. [Part (b) courtesy of N. Hirokawa; Part (c) courtesy of J. V. Small.]

to a bacterial gene that has evolved to have a role in bacterial cell-wall synthesis. Some single-celled eukaryotes, such as yeasts and amebas, have one or two ancestral actin genes, whereas multicellular organisms often contain multiple actin genes. For instance, humans have six actin genes, and some plants have more than 60 actin genes (although most are pseudogenes, which do not encode functional actin proteins). Each functional actin gene encodes a different isoform of the protein. Actin isoforms can be classified into three groups: the α -actins, β -actins, and γ -actins. In vertebrates, four actin isoforms are present in specific types of muscle cells, and two isoforms are found in nonmuscle cells. These six isoforms differ at only about 25 of the 375 residues in the complete protein, or show about 93 percent identity. Although these differences may seem minor, the three types of isoforms have different functions: α -actin is associated with contractile structures, γ -actin accounts for filaments in stress fibers, and β -actin is enriched in the cell cortex and leading edge of motile cells.

G-Actin Monomers Assemble into Long, Helical F-Actin Polymers

Actin exists as a globular monomer called G-actin and as a filamentous polymer called F-actin, which is a linear chain of G-actin subunits. Each actin molecule contains a Mg^{2+} ion complexed with either ATP or ADP. The importance of the interconversion between the ATP and the ADP forms of actin is discussed later.

X-ray crystallographic analysis reveals that the G-actin monomer is separated into two lobes by a deep cleft (Figure 17-5a). At the base of the cleft is the *ATPase fold*, the site where ATP and Mg^{2+} are bound. The floor of the cleft acts as a hinge that allows the lobes to flex relative to each other. When ATP or ADP is bound to G-actin, the nucleotide affects the conformation of the molecule; in fact, without a bound nucleotide, G-actin denatures very quickly. The addition of cations— Mg^{2+} , K^+ , or Na^+ —to a solution of G-actin will induce the polymerization of G-actin into F-actin filaments. The process is reversible: F-actin depolymerizes into G-actin when the ionic strength of the solution is lowered. The F-actin filaments that form in vitro are indistinguishable from microfilaments seen in cells, indicating that F-actin is the major component of microfilaments.

From the results of x-ray diffraction studies of actin filaments and the actin monomer structure shown in Figure 17-5a, scientists have determined that the subunits in an actin filament are arranged in a helical structure (Figure 17-5b). In this arrangement, the filament can be considered as two helical strands wound around each other. Each subunit in the structure contacts one subunit above, one below in one strand, and two in the other strand. The subunits in a single strand wind around the back of the other strand and repeat after 72 nm or 14 actin subunits. Since there are two strands, the actin filament appears to repeat every 36 nm (see Figure 17-5b). When F-actin is negatively stained with uranyl acetate for electron microscopy, it appears as a twisted string whose diameter varies between 7 and 9 nm (Figure 17-5c).

FIGURE 17-5 Structures of monomeric G-actin and F-actin filaments. (a) Model of actin monomer (measuring $5.5 \times 5.5 \times 3.5$ nm) shows that it is divided by a central cleft into two approximately equal-sized lobes and four subdomains, numbered I–IV. ATP (red) binds at the bottom of the cleft and contacts both lobes (the yellow ball represents Mg^{2+}). The N- and C-termini lie in subdomain I. (b) An actin filament appears as two strands of subunits. One repeating unit consists of 28 subunits (14 in each strand, indicated by * for one strand), covering a distance of 72 nm. The ATP-binding cleft of every actin

subunit is oriented toward the same end of the filament. The end of a filament with an exposed binding cleft is the (–) end; the opposite end is the (+) end. (c) In the electron microscope, negatively stained actin filaments appear as long, flexible, and twisted strands of beaded subunits. Because of the twist, the filament appears alternately thinner (7-nm diameter) and thicker (9-nm diameter) (arrows). (The microfilaments visualized in a cell by electron microscopy are F-actin filaments plus any bound proteins.) [Part (a) adapted from C. E. Schutt et al., 1993, *Nature* 365:810, courtesy of M. Rozycki. Part (c) courtesy of R. Craig.]

F-Actin Has Structural and Functional Polarity

All subunits in an actin filament are oriented the same way. Consequently, a filament exhibits polarity; that is, one end differs from the other. As we will see, one end of the filament is favored for the addition of actin subunits and is designated the (+) end, whereas the other end is favored for subunit dissociation, designated the (–) end. At the (+) end, the ATP-binding cleft of the terminal actin subunit contacts the neighboring subunit, whereas on the (–) end, the cleft is exposed to the surrounding solution (see Figure 17-5b).

Without the atomic resolution afforded by x-ray crystallography, the cleft in an actin subunit and therefore the polarity of a filament is not detectable. However, the polarity

of actin filaments can be demonstrated by electron microscopy in “decoration” experiments, which exploit the ability of the motor protein myosin to bind specifically to actin filaments. In this type of experiment, an excess of myosin S1, the actin-binding head domain of myosin, is mixed with actin filaments and binding is permitted to take place. Myosin attaches to the sides of a filament with a slight tilt. When all the actin subunits are bound by myosin, the filament appears “decorated” with arrowheads that all point toward one end of the filament (Figure 17-6).

The ability of the myosin S1 head to bind and coat F-actin is very useful experimentally—it has allowed researchers to identify the polarity of actin filaments, both in vitro

EXPERIMENTAL FIGURE 17-6 Myosin S1 decoration demonstrates the polarity of an actin filament. Myosin S1 head domains bind to actin subunits in a particular orientation. When bound to all the subunits in a filament, S1 appears to spiral around the filament. This coating of myosin heads produces a series of arrowheadlike decorations (arrows), most easily seen at the wide views of the filament. The polarity in decoration defines a pointed (–) end and a barbed (+) end. [Courtesy of R. Craig.]

and in cells. The arrowhead points to the (–) end, and so the (–) end is often called the “pointed” end of an actin filament; the (+) end is known as the “barbed” end. Because myosin binds to actin filaments and not to microtubules or intermediate filaments, arrowhead decoration is one criterion by which actin filaments can be definitively identified among the other cytoskeletal fibers in electron micrographs of cells.

KEY CONCEPTS of Section 17.1

Microfilaments and Actin Structures

- Microfilaments can be assembled into diverse structures, many associated with the plasma membrane (see Figure 17-4a).
- Actin, the basic building block of microfilaments, is a major protein of eukaryotic cells and is highly conserved.
- Actin can reversibly assemble into filaments that consist of two helices of actin subunits.
- The actin subunits in a filament are all oriented in the same direction, with the nucleotide-binding site exposed on the (–) end (see Figure 17-5).

17.2 Dynamics of Actin Filaments

The actin cytoskeleton is not a static, unchanging structure consisting of bundles and networks of filaments. Although microfilaments may be relatively static in some structures, in others they are highly dynamic, growing or shrinking in length. These changes in the organization of actin filaments can generate forces that cause large changes in the shape of a cell or drive intracellular movements. In this section, we consider the mechanism and regulation of actin polymerization, which is largely responsible for the dynamic nature of cells. We will see that several actin-binding proteins make important contributions to these processes.

Actin Polymerization in Vitro Proceeds in Three Steps

The in vitro polymerization of G-actin monomers to form F-actin filaments can be monitored by viscometry, sedimentation, fluorescence spectroscopy, or fluorescence microscopy (Chapter 9). When actin filaments grow long enough to become entangled, the viscosity of the solution increases, which is measured as a decrease in its flow rate in a viscometer. The basis of the sedimentation assay is the ability of ultracentrifugation (100,000g for 30 minutes) to sediment F-actin but not G-actin. The third assay makes use of G-actin covalently labeled with a fluorescent dye; the fluorescence spectrum of the labeled G-actin monomer changes when it is polymerized into F-actin. Finally, growth of the fluorescently

labeled filaments can be imaged with fluorescence video microscopy. These assays are useful for kinetic studies of actin polymerization and for characterization of actin-binding proteins to determine how they affect actin dynamics or how they cross-link actin filaments.

The mechanism of actin assembly has been studied extensively. Remarkably, one can purify G-actin at a high protein concentration without it forming filaments—provided it is maintained in a buffer with ATP and low levels of cations. However, as we saw earlier, if the cation level is increased (e.g., to 100 mM K^+ and 2 mM Mg^{2+}), G-actin will polymerize, with the kinetics of the reaction depending on the starting concentration of G-actin. The polymerization of pure G-actin in vitro proceeds in three sequential phases (Figure 17-7a):

1. The *nucleation phase* is marked by a lag period in which G-actin subunits combine into two or three subunits. When the oligomer reaches three subunits in length, it can act as a seed, or nucleus, for the next phase.
2. During the *elongation phase*, the short oligomer rapidly increases in length by the addition of actin monomers to both of its ends. As F-actin filaments grow, the concentration of G-actin monomers decreases until equilibrium is reached between the filament ends and monomers, and a steady state is reached.
3. In the *steady-state phase*, G-actin monomers exchange with subunits at the filament ends, but there is no net change in the total length of filaments.

The kinetic curves in Figure 17-7b, c show the state of filament mass during each phase of polymerization. In Figure 17-7c we see that the lag period is due to nucleation, because it can be eliminated by the addition of a small number of F-actin nuclei to the solution of G-actin.

How much G-actin is required for spontaneous filament assembly? Scientists have placed various concentrations of ATP-G-actin under polymerizing conditions and found that, below a certain concentration, filaments cannot assemble (Figure 17-8). Above this concentration, filaments begin to form, and when steady state is reached, the incorporation of more free subunits is balanced by the dissociation of subunits from filament ends to yield a mixture of filaments and monomers. The concentration at which filaments are formed is known as the overall *critical concentration*, C_c . Below C_c , filaments will not form; above C_c , filaments form. At steady state, the concentration of monomeric actin remains at the critical concentration (see Figure 17-8).

Actin Filaments Grow Faster at (+) Ends Than at (–) Ends

We saw earlier that myosin S1 head decoration experiments reveal an inherent structural polarity of F-actin (see Figure 17-6). If free ATP-G-actin is added to a preexisting myosin-decorated filament, the two ends grow at very different rates

FIGURE 17-7 The three phases of in vitro G-actin polymerization.

(a) In the initial nucleation phase, ATP-G-actin monomers (red) slowly form stable complexes of actin (purple). These nuclei are rapidly elongated in the second phase by the addition of subunits to both ends of the filament. In the third phase, the ends of actin filaments are

in a steady state with monomeric G-actin. (b) Time course of the in vitro polymerization reaction reveals the initial lag period associated with nucleation, the elongation phase, and steady state. (c) If some short, stable actin filament fragments are added at the start of the reaction to act as nuclei, elongation proceeds immediately, without any lag period.

(Figure 17-9). In fact, the rate of addition of ATP-G-actin is nearly 10 times faster at the (+) end than at the (-) end. The rate of addition is, of course, determined by the concentration of free ATP-G-actin. Kinetic experiments have shown that the rate of addition at the (+) end is about $12 \mu\text{M}^{-1} \text{s}^{-1}$ and about $1.3 \mu\text{M}^{-1} \text{s}^{-1}$ at the (-) end (Figure 17-10a). This means that if $1 \mu\text{M}$ free ATP-G-actin is added to preformed filaments, on average 12 subunits will be added to the (+) end every second, whereas only 1.3 will be added at the (-) end every second. What about the rate of subunit loss from each end? By contrast, the rates of dissociation of ATP-G-actin subunits from the two ends are quite similar, about 1.4s^{-1}

from the (+) end and 0.8s^{-1} from the (-) end. Since this dissociation is simply the rate at which subunits leave ends, it does not depend on the concentration of free ATP-G-actin.

What implications do these association and dissociation rates have for actin dynamics? First let's consider just one end, the (+) end. As we noted above, the rate of addition

FIGURE 17-8 Determination of filament formation by actin concentration. The critical concentration (C_c) is the concentration of G-actin monomers in equilibrium with actin filaments. At monomer concentrations below the C_c , no polymerization takes place. When polymerization is induced at monomer concentrations above the C_c , filaments assemble until steady state is reached and the monomer concentration falls to C_c .

EXPERIMENTAL FIGURE 17-9 The two ends of a myosin-decorated actin filament grow unequally. When short actin filaments are decorated with a myosin S1 head and then used to nucleate actin polymerization, the resulting actin subunits add much more efficiently to the (+) end than the (-) end of the nucleating filament. This result indicates that G-actin monomers are added much faster at the (+) end than at the (-) end. [Courtesy of T. Pollard.]

depends on the free ATP-G-actin concentration, whereas the rate of loss of subunits does not. Thus subunits will be added at high free ATP-G-actin concentrations, but as the concentration is lowered, a point will be reached at which the rate of addition is balanced by the rate of loss and no net growth occurs at that end. This is called the critical concentration C_c^+ for the (+) end, and we can calculate it by setting the rate of assembly equal to the rate of disassembly. Thus at the

critical concentration, the rate of assembly is C_c^+ times the measured rate of addition of $12 \mu\text{M}^{-1} \text{s}^{-1}$ ($C_c^+ 12 \text{s}^{-1}$), whereas the rate of disassembly is independent of the free actin concentration, namely, 1.4s^{-1} . Setting these equal to each other yields $C_c^+ = 1.4 \text{s}^{-1} / 12 \mu\text{M}^{-1} \text{s}^{-1}$ or $0.12 \mu\text{M}$ for the (+) end. Above this free ATP-G-actin concentration, subunits add to the (+) end and net growth occurs, whereas below it, there is a net loss of subunits and shrinkage occurs.

Now let's consider just the (-) end. Because the rate of addition is much lower, $1.3 \mu\text{M}^{-1} \text{s}^{-1}$, yet the rate of disassembly is about the same, 0.8s^{-1} , we expect the critical concentration C_c^- at the (-) end to be higher than C_c^+ . Indeed, as we just did for the (+) end, we can calculate C_c^- to be about $0.8 \text{s}^{-1} / 1.3 \mu\text{M}^{-1} \text{s}^{-1}$, or $0.6 \mu\text{M}$. Thus at less than $0.6 \mu\text{M}$ free ATP-G-actin, say, $0.3 \mu\text{M}$, the (-) end will lose subunits. But notice that at this concentration the (+) end will grow, since $0.3 \mu\text{M}$ is above C_c^+ . Because the critical concentrations are different, at steady state the free ATP-G-actin will be intermediate between C_c^+ and C_c^- , so the (+) end will grow and the (-) end will lose subunits. This phenomenon is known as *treadmilling*, because particular subunits, such those shown in blue in Figure 17-10b, appear to move through the filament.

The ability of actin filaments to treadmill is powered by hydrolysis of ATP. When ATP-G-actin binds to a (+) end, ATP is hydrolyzed to ADP and P_i . The P_i is slowly released from the subunits in the filament, so that the filament becomes asymmetric, with ATP-actin subunits at the (+) end of the filament followed by a region with ADP- P_i -actin and then, after P_i release, ADP-actin subunits toward the (-)

FIGURE 17-10 Actin treadmilling. ATP-actin subunits add faster at the (+) end than at the (-) end of an actin filament, resulting in a lower critical concentration and treadmilling at steady state. (a) The rate of addition of ATP-G-actin is much faster at the (+) end than at the (-) end, whereas the rate of dissociation of ADP-G-actin is similar at the two ends. This difference results in a lower critical concentration at the

(+) end. At steady state, ATP-actin is added preferentially at the (+) end, giving rise to a short region of the filament containing ATP-actin and regions containing ADP- P_i -actin and ADP-actin toward the (-) end. (b) At steady state, ATP-G-actin subunits add preferentially to the (+) end, while ADP-G-actin subunits disassemble from the (-) end, giving rise to treadmilling of subunits.

end (see Figure 17-10a). During hydrolysis of ATP and subsequent release of P_i from subunits in a filament, actin undergoes a conformational change that is responsible for the different association and dissociation rates at the two ends. Here we have considered only the kinetics of ATP-G-actin, but in reality it is ADP-G-actin that dissociates from the (-) end. Our analysis also relies on a plentiful supply of ATP-G-actin, which, as we will see, turns out to be the case in vivo. Thus actin can use the power generated by hydrolysis of ATP to treadmill, and treadmilling filaments can do work in vivo, as we will see later.

Actin Filament Treadmilling Is Accelerated by Profilin and Cofilin

Measurements of the rate of actin treadmilling in vivo show that it can be several times higher than can be achieved with pure actin in vitro under physiological conditions. Consistent with a treadmilling model, growth of actin filaments in vivo only ever occurs at the (+) end. How is enhanced treadmilling achieved, and how does the cell recharge the ADP-actin dissociating from the (-) end to ATP-actin for assembly at the (+) end? Two different actin-binding proteins make important contributions to these processes.

The first is *profilin*, a small protein that binds G-actin on the side opposite to the nucleotide-binding cleft. When profilin binds ADP-actin, it opens the cleft and greatly enhances the loss of ADP, which is replaced by the more abundant cellular ATP, yielding a profilin-ATP-actin complex. This complex cannot bind to the (-) end because profilin blocks the sites on G-actin for (-) end assembly. However, the profilin-ATP-actin complex can bind efficiently to the (+) end, and profilin dissociates after the new actin subunit is bound (Figure 17-11). This function of profilin on its own does not enhance treadmilling rate, but it does provide a supply of ATP-actin from released ADP-actin; as a consequence, essentially all the free G-actin in a cell has bound ATP.

Profilin has another important property: it can bind other proteins with sequences rich in proline residues at the same time as binding actin. We will see later how this property is important in actin filament assembly.

Cofilin is also a small protein involved in actin treadmilling, but it binds specifically to F-actin in which the subunits contain ADP, which are the older subunits in the filament toward the (-) end (see Figure 17-10a). Cofilin binds by bridging two actin monomers and inducing a small change in the twist of the filament. This small twist destabilizes the filament, breaking it into short pieces. By breaking the filament in this way, cofilin generates many more free (-) ends and therefore greatly enhances the disassembly of the (-) end of the filament (see Figure 17-11). The released ADP-actin subunits are then recharged by profilin and added to the (+) end as described above. In this way, profilin and cofilin can enhance treadmilling in vitro more than tenfold, up to levels seen in vivo. As might be anticipated, the cell

FIGURE 17-11 Regulation of filament formation by actin-binding proteins. Actin-binding proteins regulate the rate of assembly and disassembly as well as the availability of G-actin for polymerization. In the profilin cycle **1**, profilin binds ADP-G-actin and catalyzes the exchange of ADP for ATP. The ATP-G-actin-profilin complex can deliver actin to the (+) end of a filament with dissociation and recycling of profilin. In the cofilin cycle **2**, cofilin binds preferentially to filaments containing ADP-actin, inducing them to fragment and thus enhancing depolymerization by making more filament ends. In the thymosin-β₄ cycle **3**, G-actin available from the actin-profilin equilibrium is bound by thymosin-β₄, sequestering it from polymerization. As the free G-actin concentration is lowered by polymerization, G-actin-thymosin-β₄ dissociates to make free G-actin available for association with profilin and further polymerization.

uses signal-transduction pathways to regulate both profilin and cofilin, and thereby the turnover of actin filaments.

Thymosin-β₄ Provides a Reservoir of Actin for Polymerization

It has long been known that cells often have a very large pool of unpolymerized actin, sometimes as much as half the actin in the cell. Since cellular actin levels can be as high as 100–400 μM, this means that there can be 50–200 μM unpolymerized actin in cells. Since the critical concentration in vitro is about 0.2 μM, why doesn't all this actin polymerize? The answer lies, at least in part, in the presence of actin

monomer sequestering proteins. One of these is *thymosin- β_4* , a small protein that binds to ATP-G-actin in such a way that it inhibits addition of the actin subunit to either end of the filament. Thymosin- β_4 can be very plentiful, for example, in human blood platelets. These discoid-shaped cell fragments are very abundant in the blood, and when they are activated during blood clotting, they undergo a burst of actin assembly. Platelets are rich in actin: they are estimated to have a total concentration of about 550 μM actin, of which about 220 μM is in the unpolymerized form. They also contain about 500 μM thymosin- β_4 , which sequesters much of the free actin. However, as in any protein-protein interaction, free actin and free thymosin- β_4 are in a dynamic equilibrium with the actin-thymosin- β_4 . If some of the free actin is used up for polymerization, more actin-thymosin- β_4 will dissociate, providing more free actin for polymerization (see Figure 17-11). Thus thymosin- β_4 behaves as a buffer of unpolymerized actin for when it is needed.

Capping Proteins Block Assembly and Disassembly at Actin Filament Ends

The treadmilling and dynamics of actin filaments are further regulated in cells by *capping proteins* that specifically bind to the ends of the filaments. If this were not the case, actin filaments would continue to grow and disassemble in an uncontrolled manner. As one might expect, two classes of proteins have been discovered: ones that bind the (+) end and ones that bind the (–) end (Figure 17-12).

A protein known as *CapZ*, consisting of two closely related subunits, binds with a very high affinity ($\approx 0.1 \text{ nM}$) to the (+) end of actin filaments, thereby inhibiting subunit addition or loss. The concentration of CapZ in cells is generally sufficient to rapidly cap any newly formed (+) ends. So how can filaments grow at their (+) ends? At least two mecha-

nisms regulate the activity of CapZ. First, the capping activity of CapZ is inhibited by the regulatory lipid PI(4,5)P₂, found in the plasma membrane (Chapter 16). Second, recent work has shown that certain regulatory proteins are able to bind the (+) end and simultaneously protect it from CapZ while still allowing assembly there. Thus cells have evolved an elaborate mechanism to block assembly of actin filaments at their (+) ends except when and where assembly is needed.

Another protein called *tropomodulin* binds to the (–) end of actin filaments, also inhibiting assembly and disassembly. This protein is found predominantly in cells in which actin filaments need to be highly stabilized. Two examples we will encounter later in this chapter are the short actin filaments in the cortex of the red blood cell and the actin filaments in muscle. As we will see, in both cases tropomodulin works with another protein, tropomyosin, which lies along the filament to stabilize it. Tropomodulin binds to both tropomyosin and actin at the (–) end to greatly stabilize the filament.

In addition to CapZ, another class of proteins can cap the (+) ends of actin filaments. These proteins also can sever actin filaments. One member of this family, *gelsolin*, is regulated by increased levels of Ca^{2+} ions. On binding Ca^{2+} , gelsolin undergoes a conformational change that allows it to bind to the side of an actin filament and then insert itself between subunits of the helix, thereby breaking the filament. It then remains bound to and caps the (+) end, generating a new (–) end that can disassemble. As we discuss in a later section, actin cross-linking proteins can provide linkages between individual actin filaments to turn a solution of F-actin into a gel. If gelsolin is added to such a gel, and the level of Ca^{2+} is elevated, gelsolin will sever the actin filaments and turn it back into a liquid solution. This ability to turn a gel into a sol is why the protein was named “gelsolin.”

FIGURE 17-12 Capping proteins. Capping proteins block assembly and disassembly at filament ends. CapZ blocks the (+) end, which is where filaments normally grow, so its function is to limit actin dynamics to the (–) end. The capping protein tropomodulin blocks (–) ends, where filament disassembly normally occurs; thus the major function of tropomodulin is to stabilize filaments.

KEY CONCEPTS of Section 17.2

Dynamics of Actin Filaments

- The rate-limiting step in actin assembly is the formation of a short actin oligomer (nucleus) that can then be elongated into filaments.
- The critical concentration (C_c) is the concentration of free G-actin at which the assembly onto a filament end is balanced by loss from that end.
- When the concentration of G-actin is above the C_c , the filament end will grow; when it is less than the C_c , the filament will shrink (see Figure 17-8).
- ATP-G-actin adds much faster at the (+) end than at the (–) end, resulting in a lower critical concentration at the (+) end than at the (–) end.
- At steady state, actin subunits treadmill through a filament. ATP-actin is added at the (+) end, ATP is then hydrolyzed to ADP and P_i , P_i is lost, and ADP-actin dissociates from the (–) end.

- The length and rate of turnover of actin filaments is regulated by specialized actin-binding proteins (see Figure 17-11). Profilin enhances the exchange of ADP for ATP on G-actin; cofilin enhances the rate of loss of ADP-actin from the filament (–) end, and thymosin- β_4 binds G-actin to provide reserve actin when it is needed. Capping proteins bind to filament ends, blocking assembly and disassembly.

17.3 Mechanisms of Actin Filament Assembly

The rate-limiting step of actin polymerization is the formation of an initial actin nucleus from which a filament can grow (see Figure 17-7a). In cells, this inherent property of actin is used as a control point to determine where actin filaments are assembled—this is how the different actin assemblies within a single cell are generated (see Figures 17-1 and 17-4). Two major classes of *actin nucleating proteins*, the *formin* protein family and the *Arp2/3 complex*, nucleate actin assembly under the control of signal-transduction pathways. Moreover, they nucleate the assembly of different actin organizations: formins lead to the assembly of long actin filaments, whereas the Arp2/3 complex leads to branched networks. We will discuss each separately and see

how the power of actin polymerization can drive motile processes in a cell. We will then touch on the recent discoveries of new, specialized actin nucleating factors.

Formins Assemble Unbranched Filaments

Formins are found in essentially all eukaryotic cells as quite a diverse family of proteins; seven different classes are present in vertebrates. Although they are diverse, all formin family members have two adjacent domains in common, the so-called FH1 and FH2 domains (formin-homology domains 1 and 2). Two FH2 domains from two individual monomers associate to form a doughnut-shaped complex (Figure 17-13a). This complex has the ability to nucleate actin assembly by binding two actin subunits, holding them so that the (+) end is toward the FH2 domains. The nascent filament can now grow at the (+) end while the FH2 domain dimer remains attached. How is this possible? As we saw earlier, an actin filament can be thought of as two intertwined strands of subunits. The FH2 dimer can bind to the two terminal subunits. It then probably rocks between the two end subunits, letting go of one to allow addition of a new subunit and then binding the newly added subunit and freeing up space for the addition of another subunit to the other strand. In this way, rocking between the two subunits on the end, it can remain attached while simultaneously allowing growth at the (+) end (see Figure 17-13a).

FOCUS ANIMATION: Elongation of Actin Filament by Formin FH2 Dimer

FIGURE 17-13 Actin nucleation by the formin FH2 domain.

(a) Formins have a domain called FH2 that can form a dimer and nucleate filament assembly. The dimer binds two actin subunits (step 1), and, by rocking back and forth (steps 2–4), can allow insertion of additional subunits between the FH2 domain and the (+) end of the growing filament. The FH2 domain protects the (+)

end from being capped by capping proteins. (b) The FH2 domain of a formin was labeled with colloidal gold (black dot) and used to nucleate assembly of an actin filament. The resulting filament was visualized by electron microscopy after staining with uranyl acetate. Formins assemble long unbranched filaments. [Part (b) from D. Pruyne et al., 2002, *Science* 297:612.]

FIGURE 17-14 Regulation of formins by an intramolecular interaction. Some of the formin classes found in vertebrates are regulated by an intramolecular interaction. The inactive formin is activated by binding its Rho-binding domain (RBD) to membrane-bound active Rho-GTP, resulting in exposure of the formin's FH2 domain, which can then nucleate the assembly of a new filament. All formins have an FH1 domain adjacent to the FH2 domain; the proline-rich FH1 domain is a site for recruitment of profilin-ATP-G-actin complexes that can then be "fed" into the growing (+) end. For simplicity of representation, a single formin protein is shown, but as shown in Figure 17-13, the FH2 domain functions as a dimer to nucleate actin assembly. Regulation of the Rho family of small GTPases is detailed in Figure 17-42.

The FH1 domain adjacent to the FH2 domain also makes an important contribution to actin filament growth (Figure 17-14). This domain is rich in proline residues that are sites for the binding of several profilin molecules. We discussed earlier how profilin can exchange the ADP nucleotide on G-actin to generate profilin-ATP-actin. The FH1 domain behaves as a landing site to increase the local concentration of profilin-ATP-G-actin complexes. The actin from the localized profilin-actin complexes is fed into the FH2 domain to add actin to the (+) end of the filament with the concomitant release of profilin, thereby allowing rapid FH2-mediated filament assembly (see Figure 17-14). Since the formin allows addition of actin subunits to the (+) end, long filaments with a formin at their (+) end are generated (Figure 17-13b). In this manner, formins nucleate actin assembly and have the remarkable ability to remain bound to the (+) end while also allowing rapid assembly there. To ensure the continued growth of the filament, formins bind to the (+) end in such a way that precludes binding of a (+) end capping protein such as CapZ, which would normally terminate assembly.

To be useful to a cell, formin activity has to be regulated. Many formins exist in a folded inactive conformation as a result of an interaction between the first half of the protein and the C-terminal tail. These formins are activated by membrane-bound Rho-GTP, a Ras-related small GTPase (discussed in Section 17.7). When Rho is switched from the inactive Rho-GDP form into its activated Rho-GTP state, it can bind and activate the formin (see Figure 17-14).

Recent studies have shown that formins are responsible for the assembly of long actin filaments such as those found in stress fibers, filopodia, and in the contractile ring during cytokinesis (see Figure 17-4). The actin-nucleating role of formins was only discovered recently, so the roles performed by this diverse protein family are only now being uncovered. Since there are many different formin classes in animals, it is likely that formins will be found to assemble additional actin-based structures.

The Arp2/3 Complex Nucleates Branched Filament Assembly

The Arp2/3 complex is a protein machine consisting of seven subunits, two of which are actin-related proteins ("Arp"), explaining its name (Figure 17-15a). It is found in essentially all eukaryotes, including plants, yeasts, and animal cells. The Arp2/3 complex alone is a very poor nucleator. To nucleate the assembly of branched actin, Arp2/3 needs to be activated by interacting with a *nucleation promoting factor* (NPF), in addition to associating with the side of a preexisting actin filament. Although there are many different NPFs, the major family is characterized by the presence of a region called WCA (WH2, connector, acidic). Experiments have shown that if you add the WCA domain into an actin assembly assay together with preformed actin filaments, Arp2/3 becomes a potent nucleator of further actin assembly.

How do the Arp2/3 complex and NPF nucleate filaments? The NPF binds an actin subunit through its WH2 domain and activates the Arp2/3 complex through interaction with its acidic domain. In the inactive Arp2/3 complex, the two actin-related polypeptides—Arp2 and Arp3—are in the wrong configuration to nucleate filament assembly (see Figure 17-15a). When activated by the NPF, Arp2 and Arp3 move into the correct configuration, and the complex binds the side of preexisting actin filament. The actin subunit brought in by the WH2 domain of the NPF binds to the Arp2/3 template to nucleate filament assembly at the (+) end (Figure 17-15b). This new (+) end then grows as long as ATP-G-actin is available or until it is capped by a (+) end capping protein such as CapZ. The angle between the old filament and the new one is 70° (Figure 17-15c). This is also the angle observed experimentally in branched filaments at the leading edge of motile cells, which is believed to be formed by the action of the activated Arp2/3 complex (Figure 17-15d). As we discuss in subsequent sections, the Arp2/3 complex can be used to drive actin polymerization to power intracellular motility.

Actin nucleation by the Arp2/3 complex is exquisitely controlled, and the NPFs are part of that regulatory process. One NPF is called WASp, as it is defective in patients with Wiskott-Aldrich syndrome, an X-linked disease characterized by eczema, low platelet count, and immune deficiency. WASp exists in a folded inactive conformation, so that the WCA domain is not available (Figure 17-16). One mechanism to activate the protein involves the small Ras-related GTP-binding protein Cdc42 (discussed in Section 17.7), which in the GTP-bound state binds to and opens WASp, making the WH2 actin-binding and acidic activation domains accessible.

FIGURE 17-15 Actin nucleation by the Arp2/3 complex. (a) X-ray structure of the Arp2/3 complex, with five of the subunits in gray, and the Arp2 and Arp3 subunits in green and blue. (b) To nucleate actin assembly efficiently, the activating part of an NPF is shown with its W (WH2), C (connector), and A (acidic) domains. An actin subunit binds to the W domain (step 1), and then the A domain binds the Arp2/3 complex (step 2). This interaction induces a conformational change in the Arp2/3 complex, and after binding to the side of an actin filament, the actin subunit bound to the W domain binds to the Arp2/3 complex (step 3),

which then initiates the assembly of an actin filament at the available (+) end (step 4). The Arp2/3 branch makes a characteristic 70° angle between the filaments. (c) Averaged image compiled from several electron micrographs of Arp2/3 at an actin branch. (d) Image of actin filaments in the leading edge, with a magnification and coloring of individual branched filaments. [Part (a) PDB ID 2P9L; part (c) from C. Egile et al., 2006, *PLoS Biol.* 3:e383; part (d) from T. M. Svitkina and G. G. Borisy, 1999, *J. Cell Biol.* 145:1009.]

Although formins and the Arp2/3 complex are found in fungi, plants, and animals, additional actin nucleators have recently been discovered in animal cells. One of these, called Spire, has four tandem WH2 domains, so it can bind four actin monomers. It does this in such a manner to allow the actins to assemble into a filament, although the exact mechanism remains to be understood. As actin filaments perform so many functions in cells, it is likely that additional nucleators will be discovered.

FIGURE 17-16 Regulation of the Arp2/3 complex by WASp.

WASp is inactive due to an intramolecular interaction that masks the WCA domain. On binding the membrane-bound active small G protein Cdc42-GTP (a member of the Rho family) through its Rho-binding domain (RBD), the intramolecular interaction in WASp is relieved, exposing the W domain to bind actin and the acidic A domain for activation of the Arp2/3 complex. Regulation of the Rho family of small GTPases is detailed in Figure 17-42.

Intracellular Movements Can Be Powered by Actin Polymerization

How can actin polymerization be harnessed to do work? As we have seen, actin polymerization involves the hydrolysis of actin-ATP to actin-ADP, which allows actin to grow preferentially at the (+) end and disassemble at the (-) end. If an actin filament were to become fixed in the meshwork of the cytoskeleton and you could bind and ride on the assembling (+) end, you would be transported across the cell. This is just what the intracellular bacterial parasite *Listeria monocytogenes* does to get around the cell. The study of *Listeria* motility

was, in fact, the way the nucleating activity of the Arp2/3 protein was discovered. As we shall see shortly, *Listeria* has hijacked a normal cell motility process for its own purposes; we discuss *Listeria* first, as it is currently much better understood than the normal processes that employ similar mechanisms.

Listeria is a food-borne pathogen that causes mild gastrointestinal symptoms in most adults but can be fatal to elderly or immunocompromised individuals. It enters animal cells and divides in the cytoplasm. To move from one host cell to another, it moves around the cell by polymerizing actin into a comet tail like the plume behind a rocket (Figure 17-17a, b), and when it runs into the plasma membrane, it pushes its way

VIDEO: In Vivo Assembly of Actin Tails in *Listeria*-Infected Bacteria

EXPERIMENTAL FIGURE 17-17 *Listeria* utilizes the power of actin polymerization for intracellular movement. (a) Fluorescence microscopy of a cultured cell stained with an antibody to a bacterial surface protein (red) and fluorescent phalloidin to localize F-actin (green). Behind each *Listeria* bacterium is an actin “comet tail” that propels the bacterium forward by actin polymerization. When the bacterium runs into the plasma membrane, it pushes the membrane out into a structure like a filopodium, which protrudes into a neighboring cell. (b) *Listeria* motility can be reconstituted in vitro with bacteria and just four proteins: ATP-G-actin, Arp2/3 complex, CapZ, and cofilin.

This phase micrograph shows bacteria (black), behind which are the phase-dense actin tails. (c) A model of how *Listeria* moves using just four proteins. The ActA protein on the cell surface activates the Arp2/3 complex to nucleate new filament assembly from preexisting filaments. Filaments grow at their (+) end until capped by CapZ. Actin is recycled through the action of cofilin, which enhances depolymerization at the (-) end of the filaments. In this way, polymerization is confined to the back of the bacterium, which propels it forward. [Part (a) courtesy of J. Theriot and T. Michison; part (b) from T. P. Loisel et al., 1999, *Nature* 401:613.]

into the adjacent cell to infect it. How does it recruit the host cell actin to propel itself? *Listeria* has on its surface a protein called ActA that mimics an NPF by having an actin-binding site and an acidic region to activate the Arp2/3 complex (Figure 17-17c). The ActA protein also binds a protein known as VASP, which has three important properties. First, VASP has a proline-rich region that can bind profilin-ATP-actin for enhancing ATP-actin assembly into the newly formed barbed ends generated by the Arp2/3 complex. Second, it can hold on to the end of the newly formed filament. Third, it can protect the (+) end of the growing filament from capping by CapZ. These properties allow VASP to enhance actin assembly and confine it to the rear of the bacterium. The assembling filaments then push on the bacterium. Since the filaments are embedded in the stationary cytoskeletal matrix of the cell, the *Listeria* cell is pushed forward, ahead of the polymerizing actin. Researchers have reconstituted *Listeria* motility in the test tube using purified proteins to see what the minimal requirements for *Listeria* motility are. Remarkably, the bacteria will move when just four proteins are added: ATP-G-actin, the Arp2/3 complex, CapZ, and cofilin (see Figure 17-17b, c). We have discussed the role of actin and Arp2/3, but why are CapZ and cofilin needed? As we have seen earlier, CapZ rapidly caps the free (+) end of actin filaments, so when a growing filament no longer contributes to bacterial movement, it is rapidly capped and inhibited from further elongation. In this way, assembly occurs only adjacent to the bacterium where ActA is stimulating the Arp2/3 complex. Cofilin is necessary to accelerate the disassembly of the (–) end of the actin filament, regenerating

free actin to keep the polymerization cycle going (see Figure 17-11). This minimal rate of motility can be increased by the presence of other proteins, such as VASP and profilin, as mentioned above.

To move inside cells, the *Listeria* bacterium, as well as other opportunistic pathogens such as the *Shigella* species that cause dysentery, hijacks a normal, regulated cellular process involved in cell locomotion. As we discuss in more detail later (Section 17.7), moving cells have a thin sheet of cytoplasm that protrudes from the front of the cell called the leading edge (see Figures 17-1c, 17-4, and 17-15d). This thin sheet of cytoplasm consists of a dense meshwork of actin filaments that are continually elongating at the front of the cell to push the membrane forward. Factors in the leading-edge membrane activate the Arp2/3 complex to nucleate these filaments. Thus the power of actin assembly pushes the membrane forward to contribute to cell locomotion.

Microfilaments Function in Endocytosis

As we saw in Chapter 14, endocytosis describes the processes that cells use to take up particles, molecules, or fluid from the external medium by enclosing them in plasma membrane and then internalizing them. The uptake of molecules or liquid is called receptor-mediated or fluid-phase endocytosis, and the uptake of large particles is called phagocytosis (“cell eating”). Microfilaments participate in both of these processes.

Fluid-phase endocytosis is a very highly organized process, and recent studies have shown that the power of actin assembly contributes to this mechanism. Endocytosis assembly factors

FIGURE 17-18 Arp2/3-dependent actin assembly during endocytosis. (a) Clathrin-mediated endocytosis is a rapid and ordered process. It has been best studied in yeast, where the temporal order of specific steps has been delineated. In vivo imaging has shown that endocytosis assembly factors recruit nucleation-promoting factors that activate the Arp2/3 complex. A burst of Arp2/3-dependent actin assembly drives internalized endocytic vesicles away from the

plasma membrane, just like the movement of *Listeria*. (b) Endosome movement can be reconstituted in vitro. Endosomes isolated from cells that had taken up fluorescently labeled transferrin (red) were added to a cell extract containing fluorescently labeled actin (green). The endosomes bind WASp, which then activates the Arp2/3 complex to assemble actin tails that propel them through the cytoplasm.

[Part (b) from Taunton et al., 2000, *J. Cell Biol.* 148:519].

FIGURE 17-19 Phagocytosis and actin dynamics. Actin assembly and contraction drives the internalization of phagocytic particles. Shown here is the phagocytosis and degradation of a bacterium by a leukocyte. An invading bacterium is coated by specific antibodies to a cell-surface protein in a process known as opsonization (step **1**). The Fc region of the bound antibodies is displayed on the bacterial surface and recognized by a specific receptor, the Fc receptor, on the leukocyte surface (step **2**). This interaction signals the cell to assemble a contractile actin structure that results in the internalization and engulfment of the bacterium (step **3**). Once it has been internalized into a phagosome, the bacterium is killed and degraded by enzymes delivered from lysosomes (step **4**).

recruit NPIs so that as the endocytic vesicles invaginate and pinch off from the membrane, they are then driven into the cytoplasm, powered by a rapid and very short-lived burst (a few seconds in duration) of actin polymerization driven by the Arp2/3 complex (Figure 17-18a). This actin-based movement of endocytic vesicles involving the Arp2/3 complex can be reconstituted in vitro (Figure 17-18b) and is mechanistically very similar to leading-edge formation and *Listeria* motility.

Phagocytosis is a vital process in the recognition and removal of pathogens, such as bacteria, by white blood cells. The immune system identifies the bacterium as foreign material and makes antibodies that recognize components on its surface. As we discussed in Chapter 3, each antibody has a region called the Fab domain that binds specifically to its antigen, in this case a component on the bacterial cell surface. As antibodies coat the bacterium through interaction between their Fab domains and the cell-surface antigen, a second antibody domain known as the Fc domain is exposed. This process is known as opsonization (Figure 17-19, step **1**). The white blood cells have a receptor on their cell surface, the Fc receptor, that recognizes the antibodies on the bacterium; this interaction signals the cells to bind and engulf the pathogen (steps **2** and **3**). The signal also tells the cell to assemble microfilaments at the interaction site with the bacterium, and the assembled microfilaments, together with myosin motor proteins, provide the force necessary to draw the bacterium into the cell, ultimately fully enclosing the pathogen in plasma membrane (step **3**). Once internalized, the newly formed phagosome fuses with lysosomes, where the pathogen is killed and degraded by lysosomal enzymes.

Toxins That Perturb the Pool of Actin Monomers Are Useful for Studying Actin Dynamics

Certain fungi and sponges have developed toxins that target the polymerization cycle of actin and are therefore toxic to animal cells. Two types of toxins have been characterized. The first class is represented by two unrelated toxins, cytochalasin D and latrunculin, which promote the depolymerization of filaments, though by different mechanisms. Cytochalasin D, a fungal alkaloid, depolymerizes actin filaments by binding to the (+) end of F-actin, where it blocks further addition of subunits. Latrunculin, a toxin secreted by sponges, binds and sequesters G-actin, inhibiting it from adding to a filament end. Exposure to either toxin thus increases the monomer

pool. When cytochalasin D or latrunculin is added to live cells, the actin cytoskeleton disassembles and cell movements such as locomotion and cytokinesis are inhibited. These observations were among the first to implicate actin filaments in cell motility. Latrunculin is especially useful because it binds actin monomers and prevents any new actin assembly. Thus if you add latrunculin to a cell, the rate at which actin-based structures disappear reflects their normal rate of turnover. This has revealed that some structures have half-lives of less than a minute, whereas others are much more stable. For example, experiments with latrunculin show that the leading edge of motile cells turns over every 30–180 seconds, and stress fibers turn over every 5–10 minutes.

In contrast, the monomer-polymer equilibrium is shifted in the direction of filaments by jasplakinolide, another sponge toxin, and by phalloidin, which is isolated from *Amanita phalloides* (the “angel of death” mushroom). Jasplakinolide enhances nucleation by binding and stabilizing actin dimers and thereby lowering the critical concentration. Phalloidin binds at the interface between subunits in F-actin, locking adjacent subunits together and preventing actin filaments from depolymerizing. Even when actin is diluted below its critical concentration, phalloidin-stabilized filaments will not depolymerize. Because many actin-based processes depend on actin filament turnover, the introduction of phalloidin into a cell paralyzes all these systems and the cell dies. However, phalloidin has been very useful to researchers, as fluorescent-labeled phalloidin, which binds only to F-actin, is commonly used to stain actin filaments for light microscopy (see Figure 17-4).

KEY CONCEPTS of Section 17.3

Mechanisms of Actin Filament Assembly

- Actin assembly is nucleated by two classes of proteins: formins nucleate the assembly of unbranched filaments (see Figure 17-13), whereas the Arp2/3 complex nucleates the assembly of branched actin networks (see Figure 17-15). The activities of formins and Arp2/3 are regulated by signal-transduction pathways.
- Functionally different actin-based structures are assembled by formins and Arp2/3 nucleators. Formins drive the assembly of stress fibers and the contractile ring, whereas Arp2/3 nucleates the assembly of branched actin filaments found in the leading edge of motile cells.
- The power of actin polymerization can be harnessed to do work, as is seen in the Arp2/3-dependent intracellular movement of pathogenic bacteria (see Figure 17-17) and inward movement of endocytic vesicles (see Figures 17-18 and 17-19).
- Several toxins affect the dynamics of actin polymerization; some, such as latrunculin, bind and sequester actin monomers, whereas others, such as phalloidin, stabilize filamentous actin. Fluorescently labeled phalloidin is useful for staining actin filaments.

17.4 Organization of Actin-Based Cellular Structures

We have seen that actin filaments are assembled into a wide variety of different arrangements and how many associated proteins nucleate actin assembly and regulate filament turnover. Dozens of proteins in a vertebrate cell organize these filaments into diverse functional structures. Here we discuss just a few of these proteins, giving examples of typical types of actin cross-linking proteins found in cells, and also discuss the proteins involved in making functional links between actin and membrane proteins. One fascinating problem, about which very little is known, is how cells assemble different actin-based structures within the same cytoplasm of a cell. Some of this organization must be due to local regulation, a topic we come to at the end of the chapter.

Cross-Linking Proteins Organize Actin Filaments into Bundles or Networks

When one assembles actin filaments in a test tube, they form a tangled network. In cells, however, actin filaments are found in a variety of distinct structures, such as the highly ordered filament bundles in microvilli or the meshwork characteristic of the leading edge (see Figure 17-4a). These different organizations are determined by the presence of actin *cross-linking proteins*. To be able to organize actin, an actin cross-linking protein must have two F-actin-binding sites (Figure 17-20a).

Cross-linking of F-actin can be achieved by having two actin-binding sites within a single polypeptide, as with *fimbrin*, a protein found in microvilli that builds bundles of filaments all having the same polarity (Figure 17-20b). Other actin cross-linking proteins have a single actin-binding site in a polypeptide chain and then two chains associate to form dimers that bring together two actin-binding sites. These dimeric cross-linking proteins can assemble to generate a rigid rod connecting the two binding sites, as happens with α -*actinin*. Like fimbrin, α -actinin also bundles parallel actin filaments, but farther apart than fimbrin. Another protein, called *spectrin*, is a tetramer with two actin-binding sites; spectrin spans an even greater distance between actin filaments and makes networks under the plasma membrane (shown in Figure 17-21 and discussed in the next section). Other types of cross-linking proteins, such as *filamin*, have a highly flexible region between the two binding sites, functioning like a molecular leaf spring, so they can make stabilizing cross-links between filaments in a meshwork (Figure 17-20c), as is found in the leading edge of motile cells. The Arp2/3 complex, which we discussed in terms of its ability to nucleate actin filament assembly, is also an important cross-linking protein, attaching the (–) end of one filament to the side of another filament (see Figure 17-15).

FIGURE 17-20 Actin cross-linking proteins. Actin cross-linking proteins mold F-actin filaments into diverse structures. (a) Examples of four F-actin cross-linking proteins, all of which have two domains (blue) that bind F-actin. Some have a Ca^{2+} -binding site (purple) that inhibits their activity at high levels of free Ca^{2+} . Also shown is dystrophin, which has an actin-binding site on its N-terminal end and a C-terminal domain that binds the membrane protein dystroglycan. (b) Transmission electron

micrograph of a thin section of a stereocilium (an unfortunate name, since it is really a giant microvillus) on a sensory hair cell in the inner ear. This structure contains a bundle of actin filaments cross-linked by fimbrin, a small cross-linking protein that allows for close and regular interaction of actin filaments. (c) Long cross-linking proteins such as filamin are flexible and can thus cross-link actin filaments into a loose network. [Part (b) from L. G. Tilney, 1983, *J. Cell Biol.* **96**:822; part (c) courtesy of J. Hartwig.]

Adaptor Proteins Link Actin Filaments to Membranes

To contribute to the structure of cells and also to harness the power of actin polymerization, actin filaments are very often attached to membranes or are associated with intracellular structures. Actin filaments are especially abundant in the cell

cortex underlying the plasma membrane, to which they give support. Actin filaments can interact with membranes either laterally or at their ends.

Our first example of actin filaments attached to membranes is the human erythrocyte—the red blood cell. The erythrocyte consists essentially of plasma membrane enclosing

FIGURE 17-21 Lateral attachment of microfilaments to membranes.

(a) Electron micrograph of the erythrocyte membrane showing the spoke-and-hub organization of the cortical cytoskeleton supporting the plasma membrane in human erythrocytes. The long spokes are composed mainly of spectrin and can be seen to intersect at the hubs, or membrane-attachment sites. The darker spots along the spokes are ankyrin molecules, which cross-link spectrin to integral membrane proteins. (b) Diagram of the erythrocyte cytoskeleton, showing the two main types of membrane attachment: **1** ankyrin and **2** band 4.1. (c) Actin is incorporated into the tip of stereocilia (giant microvilli). Cells with stereocilia were transfected to express GFP-actin for a short period of time and then counterstained with

rhodamine-phalloidin to stain all the F-actin. The experiment shows that new actin is incorporated at the tips of the stereocilia. (d) Ezrin, a member of the ezrin-radixin-moesin (ERM) family, links actin filaments laterally to the plasma membrane in surface structures such as microvilli; attachment can be direct or indirect. Ezrin, activated by phosphorylation (P), links directly to the cytoplasmic region of transmembrane proteins (*right*) or indirectly through a scaffolding protein such as EBP50 (*left*). [Part (a) from T. J. Byers and D. Branton, 1985, *Proc. Nat'l Acad. Sci. USA* **82**:6153, courtesy of D. Branton; part (b) adapted from S. E. Lux, 1979, *Nature* **281**:426, and E. J. Luna and A. L. Hitt, 1992, *Science* **258**:955; part (c) from A. K. Rzaizinska et al., 2004, *J. Cell Biol.* **164**:887; (d) adapted from R. G. Fehon et al., 2010, *Nature Rev. Mol. Cell Biol.* **11**:276.]

a high concentration of the protein hemoglobin to transport oxygen from the lungs to tissues and carbon dioxide from tissues back to the lung—all powered by the magnificent muscle known as the heart. Erythrocytes must be able to survive the raging torrents of blood flow in the heart, then flow down arteries and survive squeezing through narrow capillaries before being cycled through the lungs via the heart. To survive this grueling process for thousands of cycles, erythrocytes have a microfilament-based network underlying their plasma membrane that gives them both the tensile strength and the flexibility necessary for their journey. This network is based on short actin filaments of about 14 subunits in length, stabilized on

their sides by tropomyosin (discussed in more detail in Section 17.6) and by the capping protein tropomodulin on the (–) end. These short filaments serve as hubs for binding about six flexible spectrin molecules, generating a fishing-net type of structure (Figure 17-21a). This network gives the erythrocyte both its strength and flexibility. Spectrin is attached to membrane proteins through two mechanisms: through a protein called *ankyrin* to the bicarbonate transporter (a transmembrane protein also known as *band 3*) and through a spectrin and F-actin-binding protein called *band 4.1* to another transmembrane protein called *glycophorin C* (Figure 17-21b). Although this spectrin-based network is highly developed in the

erythrocyte, similar types of linkages occur in many cell types. For example, a related type of ankyrin-spectrin attachment links the Na^+/K^+ ATPase to the actin cytoskeleton on the basolateral membrane of epithelial cells.

 Genetic defects in proteins of the red blood cell cytoskeleton can result in cells that rupture easily, giving rise to diseases known as hereditary spherocytic anemias (*spherocytic* because the cells are rounder, *anemias* because there is a shortage of red blood cells) and hence a shorter life span. In human patients, mutations in spectrin, band 4.1, and ankyrin can cause this disease. ■

In addition to the spectrin-based type of support in the cell cortex, microfilaments provide the support for cell-surface structures such as microvilli and membrane ruffles. If we look at a microvillus, it is clear that it must have an end-on attachment at the tip and lateral attachments down its length. What is the orientation of actin filaments in microvilli? Decoration of microvillar filaments by the S1 fragment of myosin show that it is the (+) end at the tip. Moreover, when fluorescent actin is added to a cell, it is incorporated at the tip of a microvillus, showing that not only is the (+) end there, actin filament assembly occurs there (Figure 17-21c). At present it is not known how actin filaments are attached at the microvillus tip, but a likely candidate is a formin protein. This (+) end orientation of actin filaments with respect to the plasma membrane is found almost universally—not just in microvilli but also, for example, in the leading edge of motile cells. The lateral attachments to the plasma membrane are provided, at least in part, by the *ERM (ezrin-radixin-moesin)* family of proteins. These are regulated proteins that exist in a folded, inactive form. When activated by phosphorylation in response to an external signal, F-actin and membrane-protein-binding sites of the ERM protein are exposed to provide a lateral linkage to actin filaments (Figure 17-21d). At the plasma membrane, ERM proteins can link the actin filaments directly or indirectly through scaffolding proteins to the cytoplasmic domain of membrane proteins.

The types of actin membrane linkages we have discussed so far do not involve areas of the plasma membrane attached directly to other cells in a tissue or to the extracellular matrix. Contact between epithelial cells is mediated by highly specialized regions of the plasma membrane called *adherens junctions* (see Figure 17-1b). Other specialized regions of association called *focal adhesions* mediate attachment of cells to the extracellular matrix. In turn, these specialized types of attachments connect to the cytoskeleton, as will be described in more detail when we discuss cell migration (Section 17.7) and cells in the context of tissues (Chapter 20).

 Muscular dystrophies are genetic diseases that are often characterized by the progressive weakening of skeletal muscle. One of these genetic diseases, Duchenne muscular dystrophy, affects the protein dystrophin, whose gene is located on the X chromosome, and so the disease is much more prevalent in males. *Dystrophin* is a modular protein

whose function is to link the cortical actin network of muscle cells to a complex of membrane proteins that link to the extracellular matrix. Thus dystrophin has an N-terminal actin-binding domain, followed by a series of spectrinlike repeats and terminating in a domain that binds the transmembrane dystroglycan complex to the extracellular matrix protein laminin (see Figure 17-20a). In the absence of dystrophin, the plasma membrane of muscle cells becomes weakened by cycles of muscle contraction and eventually ruptures, resulting in death of the muscle myofibril. ■

KEY CONCEPTS of Section 17.4

Organization of Actin-Based Cellular Structures

- Actin filaments are organized by cross-linking proteins that have two F-actin-binding sites. Actin cross-linking proteins can be long or short, rigid or flexible, depending on the type of structure involved (see Figure 17-20).
- Actin filaments are attached laterally to the plasma membrane by specific classes of proteins, as seen in the red blood cell or in cell-surface structures such as microvilli (see Figure 17-21).
- The (+) end of actin filaments can also be attached to membranes, with assembly mediated between the filament end and the membrane.
- Several diseases have been traced to defects in the microfilament-based cortical cytoskeleton that underlies the plasma membrane.

17.5 Myosins: Actin-Based Motor Proteins

In Section 17.3 we discussed how actin polymerization nucleated by the Arp2/3 complex can be harnessed to do work, such as in the movement of vesicles during endocytosis, at the leading edge of motile cells, and the propulsion of *Listeria* bacterium across the eukaryotic cell. In addition to actin-polymerization-based motility, cells have a large family of motor proteins called **myosins** that can move along actin filaments. The first myosin discovered, myosin II, was isolated from skeletal muscle. For a long time, biologists thought that this was the only type of myosin found in nature. However, they then discovered other types of myosins and began to ask how many different functional classes might exist. Today we know that there are several different classes of myosins, in addition to the myosin II of skeletal muscle, that move along actin. Indeed, with the discovery and analysis of all these actin-based motors and the corresponding microtubule-based motors described in the next chapter, the former relatively static view of a cell has been replaced with the realization that the cytoplasm is incredibly dynamic—more like an organized but busy freeway system with motors busily ferrying components around.

Myosins have the amazing ability to convert the energy released by ATP hydrolysis into mechanical work (movement along actin). All myosins convert ATP hydrolysis into work, yet different myosins can perform very different types of functions. For example, many molecules of myosin II pull together on actin filaments to bring about muscle contraction, whereas myosin V binds to vesicular cargo to transport it along actin filaments. The other classes of myosin provide a myriad of functions, from moving organelles around cells to contributing to cell migration.

To begin to understand myosins, we first discuss their general domain organization. Armed with this information, we explore the diversity of myosins in different organisms and describe in more detail some of those that are common in eukaryotes. To understand how such diverse functions

can be accommodated by one type of motor mechanism, we will investigate the basic mechanism of how the energy released by ATP hydrolysis is converted into work and then see how this mechanism is modified to tailor the properties of specific myosin classes for their specific functions.

Myosins Have Head, Neck, and Tail Domains with Distinct Functions

Much of what we know about myosins comes from studies of myosin II isolated from skeletal muscle. In skeletal muscle, hundreds of individual myosin II molecules are assembled into bundles called bipolar thick filaments (Figure 17-22a). In a later section we will discuss how these myosin filaments interdigitate with actin filaments to bring about

FIGURE 17-22 Structure of myosin II. (a) Organization of myosin II in filaments isolated from skeletal muscle. Myosin II assembles into bipolar filaments in which the tails form the shaft of the filament with heads exposed at the ends. Extraction of bipolar filaments with high salt and ATP disassembles the filament into individual myosin II molecules. (b) Myosin II molecules consist of two identical heavy chains (light blue) and four light chains (green and dark blue). The tail of the heavy chains forms a coiled coil to dimerize; the neck region of each heavy chain has two light chains associated with it. Limited proteolytic

cleavage of myosin II generates tail fragments—LMM and S2—and the S1 motor domain. (c) Three-dimensional model of a single S1 head domain shows that it has a curved, elongated shape and is bisected by a cleft. The nucleotide-binding pocket lies on one side of this cleft, and the actin-binding site lies on the other side near the tip of the head. Wrapped around the shaft of the α -helical neck are two light chains. These chains stiffen the neck so that it can act as a lever arm for the head. Shown here is the ADP-bound conformation.

muscle contraction. Here, we first investigate the properties of the individual myosin molecule itself.

It is possible to dissolve the myosin thick filament in a solution of ATP and high salt, generating a pool of individual myosin II molecules. The soluble myosin II molecule is actually a protein complex consisting of six polypeptides. Two of the subunits are identical high-molecular-weight polypeptides known as myosin heavy chains. Each consists of a globular *head* domain and a long *tail* domain, connected by a flexible *neck* domain. The tails of the two myosin heavy chains intertwine, so that the head regions are in close proximity. The remaining four subunits of the myosin complex are smaller in size and are known as the light chains. There are two types of light chain, the *essential light chain* and the *regulatory light chain*. One light chain of each type associates with the neck region of each heavy chain (Figure 17-22b, *top*). The myosin heavy chain and the two types of light chains are encoded by three different genes.

The soluble myosin II molecule has ATPase activity, reflecting its ability to power movements by hydrolysis of ATP. But which part of the myosin complex is responsible for this activity? To identify functional domains in a protein, a standard approach is to cleave the protein into fragments with specific proteases and then ask which fragments have the activity. Soluble myosin II can be cleaved by gentle treatment with the protease chymotrypsin to yield two fragments, one called heavy meromyosin (HMM; *mero* means “part of”) and the other, light meromyosin (LMM) (Figure 17-22b, *middle*). The heavy meromyosin can be further cleaved by the protease papain to yield subfragment 1 (S1) and subfragment 2 (S2) (Figure 17-22b, *bottom*). By analyzing the properties of the various fragments—S1, S2, and LMM—it was found that the intrinsic ATPase activity of myosin resides in the S1 fragment, as does its F-actin-binding site. Moreover, it was

found that the ATPase activity of the S1 fragment was greatly enhanced by the presence of filamentous actin, so it is said to have an *actin-activated ATPase activity*, which is a hallmark of all myosins. The S1 fragment of myosin II consists of the head and neck domains with associated light chains, whereas the S2 and LMM regions make up the tail domain.

X-ray crystallographic analysis of the head and neck domains revealed its shape, the positions of the light chains, and the locations of the ATP-binding and actin-binding sites (Figure 17-22c). At the base of the myosin head is the α -helical neck, where two light-chain molecules wrap around the neck like C-clamps. In this position, the light chains stiffen the neck region. The actin-binding site is an exposed region at the tip of the head domain; the ATP-binding site is also in the head domain, within a cleft opposite the actin-binding site.

How much of myosin II is necessary and sufficient for “motor” activity? To answer this question, one needs a simple *in vitro* motility assay. In one such assay, the *sliding-filament assay*, myosin molecules are tethered to a coverslip to which is added stabilized, fluorescently labeled actin filaments. Because the myosin molecules are tethered, they cannot slide; thus any force generated by interaction of myosin heads with actin filaments forces the filaments to move relative to the myosin (Figure 17-23a). If ATP is present, added actin filaments can be seen to glide along the surface of the coverslip; if ATP is absent, no filament movement is observed. Using this assay, one can show that the S1 head of myosin II is sufficient to bring about movement of actin filaments. This movement is caused by the tethered myosin S1 fragments (bound to the coverslip) trying to “move” toward the (+) end of a filament; thus the filaments move with the (–) end leading. The rate at which myosin moves an actin filament can be determined from video recordings of sliding-filament assays (Figure 17-23b).

TECHNIQUE ANIMATION: In Vitro Motility Myosin Assay

EXPERIMENTAL FIGURE 17-23 Sliding-filament assay is used to detect myosin-powered movement. (a) After myosin molecules are adsorbed onto the surface of a glass coverslip, excess unbound myosin is removed; the coverslip then is placed myosin-side down on a glass slide to form a chamber through which solutions can flow. A solution of actin filaments, made visible and stable by staining with rhodamine-labeled phalloidin, is allowed to flow into the chamber. In the presence of ATP, the myosin heads walk toward the (+) end of filaments by the mechanism illustrated in Figure 17-26. Because myosin tails are immobilized, walking of the heads toward the (+) ends causes sliding of the filaments, which appear to be moving with their (–) ends leading the way. Movement of individual filaments can be observed in a fluorescence light microscope. (b) These photographs show the positions of three actin filaments (numbered 1, 2, 3) at 30-second intervals recorded by video microscopy. The rate of filament movement can be determined from such recordings. [Part (b) courtesy of M. Footer and S. Kron.]

All myosins have a domain related to the S1 domain of myosin II, comprising the head and neck domains, which is responsible for their motor activity. However, as we will see in a later section, the length of the neck domain and the number and type of light chains associated with it varies in different myosin classes. The tail domain does not contribute to motility but rather defines what is moved by the S1-related domain. Thus, as might be expected, the tail domains can be very different and are tailored to bind specific cargoes.

Myosins Make Up a Large Family of Mechanochemical Motor Proteins

Since all myosins have related S1-motor domains with considerable similarity in primary amino acid sequence, it is possible to determine how many myosin genes, and how many different classes of myosins, exist in a sequenced genome. There are about 40 myosin genes in the human genome (Figure 17-24), nine in *Drosophila*, and five in budding yeast. Computer analysis of the sequence relationships between the myosin head domains suggests that about 20 distinct classes

FIGURE 17-24 The myosin superfamily in humans. Computer analysis of the relatedness of S1 head domains of all of the approximately 40 myosins encoded by the human genome. Each myosin is indicated by a blue dot, with the length of the black lines indicating phylogenetic distance relationships. Thus myosins connected by short lines are closely related, whereas those separated by longer lines are more distantly related. Among these myosins are three classes—myosins I, II, and V—widely represented among eukaryotes, with others having more specialized functions. Indicated are examples in which loss of a specific myosin causes a disease. [Redrawn and modified from R. E. Cheney, 2001, *Mol. Biol. Cell* 12:780.]

of myosins have evolved in eukaryotes, with greater sequence similarity within a class than between. As indicated in Figure 17-24, the genetic basis for some diseases has been traced to genes encoding myosins. All myosin head domains convert ATP hydrolysis into mechanical work using the same general mechanism. However, as we will see, subtle differences in this mechanism can have profound effects on the functional properties of different myosin classes. How do these different classes relate with respect to their tail domains? Amazingly, if one takes just the protein sequences of the tail domains of the myosins and uses this information to place them in classes, they fall into the same groupings as the motor domains. This implies that head domains with specific properties have co-evolved with specific classes of tail domains, which makes a lot of sense, suggesting that each class of myosin has evolved to carry out a specific function.

Among all these different classes of myosins are three especially well-studied ones, which are commonly found in animals and fungi: the so-called *myosin I*, *myosin II*, and *myosin V* families (Figure 17-25). In humans, eight genes encode heavy chains for the myosin I family, 14 for the myosin II family, and three for the myosin V family (see Figure 17-24).

The myosin II class assembles into bipolar filaments, with opposite orientations in each half of the bipolar filament so that there is a cluster of head domains at each end of the filament. This organization is important for its involvement in contraction; indeed, this is the only class of myosins involved in contractile functions. The large number of members in this class reflects the need for myosin II filaments with the slightly different contractile properties seen in different muscles (e.g., skeletal, cardiac, and various types of smooth muscle) as well as in nonmuscle cells.

The myosin II class is the only one that assembles into bipolar filaments. All myosin II members have a relatively short neck domain, with two light chains per heavy chain. The myosin I class is quite large, has a variable number of light chains associated with the neck region, and is the only one in which two heavy chains are not associated through their tail domains and so are single-headed. The large size and diversity of the myosin I class suggests that these myosins perform many functions, most of which remain to be determined, but some members of this family connect actin filaments to membranes, and others are implicated in endocytosis. Members of the myosin V class have two heavy chains, giving a motor with two heads, long neck regions with six light chains each, and tail regions that dimerize and terminate in domains that bind to specific organelles to be transported. As we will see shortly, the length of the neck region affects the rate of myosin movement.

In every case that has been tested so far, myosins move toward the (+) end of an actin filament—with one exception, the *myosin VI* found in animals. This remarkable myosin has an insert in its head domain to make it work in the opposite direction, and so motility is toward the (–) end of an actin filament. Myosin VI is believed to contribute to endocytosis by moving the endocytic vesicles along actin filaments away from the plasma membrane. Recall that membrane-associated

FIGURE 17-25 Three common classes of myosin. Myosin I consists of a head domain with a variable number of light chains associated with the neck domain. Members of the myosin I class are the only myosins to have a single head domain. Some of these myosins are believed to associate directly with membranes through lipid interactions. Myosin IIs

have two head domains and two light chains per neck and are the only class that can assemble into bipolar filaments. Myosin Vs have two head domains and six light chains per neck. They bind specific receptors (brown box) on organelles, which they transport. All myosins in these three classes move toward the (+) end of actin filaments.

actin filaments have their (+) ends toward the membrane, so a motor directed toward the (–) end would take them away from the membrane toward the center of the cell.

Conformational Changes in the Myosin Head Couple ATP Hydrolysis to Movement

Studies of muscle contraction provided the first evidence that myosin heads slide or walk along actin filaments. Unraveling the mechanism of muscle contraction was greatly aided by the development of in vitro motility assays and single-molecule force measurements. On the basis of information obtained with these techniques and the three-dimensional structure of the myosin head (see Figure 17-22c), researchers developed a general model for how myosin harnesses the energy released by ATP hydrolysis to move along an actin filament (Figure 17-26). Because all myosins are thought to use the same basic mechanism to generate movement, we will ignore whether the myosin tail is bound to a vesicle or is part of a thick filament, as it is in muscle. The most important aspect of this model is that the hydrolysis of a single ATP molecule is coupled to each step taken by a myosin molecule along an actin filament.

How can myosin convert the chemical energy released by ATP hydrolysis into mechanical work? This question has long intrigued biologists. It has been known for a long time that the S1 head of myosin is an ATPase, having the ability to hydrolyze ATP into ADP and P_i . Biochemical analysis revealed the mechanism of myosin movement (Figure 17-26a).

In the absence of ATP, the head of myosin binds very tightly to F-actin. When ATP binds, the affinity of the head for F-actin is greatly reduced and releases from actin. The myosin head then hydrolyzes the ATP, and the hydrolysis products, ADP and P_i , remain bound. The energy provided by the hydrolysis of ATP induces a conformational change in the head that results in the head domain rotating with respect to the neck. This is known as the “cocked” position of the head (Figure 17-26b, *top*). In the absence of F-actin, release of P_i is exceptionally slow—the slowest part of the ATPase cycle. However, in the presence of actin, the head binds F-actin tightly, inducing both release of P_i and rotation of the head back to its original position, thus moving the actin filament relative to the neck domain (Figure 17-26b, *bottom*). In this way, binding to F-actin induces the movement of the head and release of P_i , thereby coupling the two processes. This step is known as the *power stroke*. The head remains bound until the ADP leaves and a fresh ATP binds the head, releasing it from the filament. The cycle then repeats, and the myosin can move again against the filament.

How is hydrolysis of ATP in the nucleotide-binding pocket converted into force? The results of structural studies of myosin in the presence of nucleotides, and nucleotide analogs that mimic the various steps in the cycle, indicate that the binding and hydrolysis of a nucleotide cause a small conformational change in the head domain. This small movement is amplified by a “converter” region at the base of the head, acting like a fulcrum and causing the leverlike neck to rotate. This rotation is amplified by the rodlike lever arm,

FOCUS ANIMATION: Myosin-Actin Cross-Bridge Cycle
PODCAST: Myosin Movement Against Actin Filaments

FIGURE 17-26 ATP-driven myosin movement along actin filaments. (a) In the absence of ATP, the myosin head is firmly attached to the actin filament. Although this state is very short-lived in living muscle, it is the state responsible for muscle stiffness in death (rigor mortis). **Step 1:** On binding ATP, the myosin head releases from the actin filament. **Step 2:** The head hydrolyzes the ATP to ADP and P_i , which induces a rotation in the head with respect to the neck. This "cocked state" stores the energy released by ATP hydrolysis as elastic energy, like a stretched spring. **Step 3:** Myosin in the "cocked" state binds actin. **Step 4:** When it is bound to actin, the myosin head couples release of P_i with release of the elastic energy to move the actin filament. This is known as the "power stroke," as it involves moving the actin filament with respect to the end of the myosin neck domain. **Step 5:** The head remains tightly bound to the filament as ADP is released and before fresh ATP is bound by the head. (b) Molecular models of the conformational changes in the myosin head involved in "cocking" the head (upper panel) and during the power stroke (lower panel). The myosin light chains are shown in dark blue and green; the rest of the myosin head and neck are colored in light blue, and actin is red [Part (a) adapted from R. D. Vale and R. A. Milligan, 2002, *Science* **288**:88; part (b) courtesy of Mike Geeves.]

EXPERIMENTAL FIGURE 17-27 The length of the myosin II neck domain determines the rate of movement. To test the lever-arm model of myosin movement, investigators used recombinant DNA techniques to make myosin heads attached to different-length neck domains. The rate at which they moved on actin filaments was determined. The longer the lever arm, the faster the myosin moved, supporting the proposed mechanism. [Redrawn from K. A. Ruppel and J. A. Spudis, 1996, *Annu. Rev. Cell Mol. Biol.* 12:543–573.]

which constitutes the neck domain, so the actin filament moves by a few nanometers (see Figure 17-26b).

This model makes a strong prediction: the distance a myosin head moves along actin during hydrolysis of one ATP—the myosin *step size*—should be proportional to the length of the neck domain. To test this, mutant myosin molecules were constructed with different-length neck domains and the rate at which they moved down an actin filament was determined. Remarkably, there is an excellent correspondence between the length of the neck domain and the rate of movement (Figure 17-27).

Myosin Heads Take Discrete Steps Along Actin Filaments

The most critical feature of myosin is its ability to generate a force that powers movements. Researchers have used *optical traps* to measure the forces generated by single myosin molecules (Figure 17-28). In this approach, myosin is immobilized on beads at a low density. An actin filament, held between two optical traps, is lowered toward the bead until it contacts a myosin molecule on the bead. When ATP is added, the myosin pulls on the actin filament. Using a mechanical feedback mechanism controlled by a computer, one can measure the distance pulled and the forces and duration of the movement. The results of optical trap studies show that myosin II does not interact with the actin filament continuously but rather binds, moves, and releases it. In fact, myosin II spends on average only about 10 percent of each ATPase cycle in contact with F-actin—it is said to have a *duty ratio* of 10 percent. This

FIGURE 17-28 Optical trapping of actin. Optical trap techniques can be used to determine the step size and force generated by a single myosin molecule. In an optical trap, the beam of an infrared laser is focused by a light microscope on a latex bead (or any other object that does not absorb infrared light), which captures and holds the bead in the center of the beam. The strength of the force holding the bead is adjusted by increasing or decreasing the intensity of the laser beam. In this experiment, an actin filament is held between two optical traps. The actin filament is then lowered onto a third bead coated with a dilute concentration of myosin molecules. If the actin filament encounters a myosin molecule in the presence of ATP, the myosin will pull on the actin filament, which allows the investigators to measure both the force generated and the step size the myosin takes.

will be important later when we consider that in contracting muscle, hundreds of myosin heads pull on actin filaments, so that at any one time, 10 percent of the heads are engaged to provide a smooth contraction.

When myosin II does contact F-actin, it takes discrete steps, which average out to about 8 nm (Figure 17-29, *top*), and generates 3–5 piconewtons (pN) of force, approximately the same force as that exerted by gravity on a single bacterium.

If we now look at a similar optical trap experiment with myosin V, the curves look completely different (Figure 17-29, *bottom*). Now we can easily discern clear steps of about 36 nm in length. This larger step size reflects the longer neck domain—the lever arm—of myosin V. Moreover, we see that the motor takes many sequential steps without releasing from the actin—it is said to move *processively*. This is because its ATPase cycle is modified to have a much higher duty ratio (>70 percent) by slowing the rate of ADP release; thus the head remains in contact with the actin filament for a much larger percentage of the cycle. Since a single myosin V molecule has two heads, a duty ratio of >50 percent ensures that one head is in contact at all times as it moves down an actin filament, so that it does not fall off.

Myosin V Walks Hand over Hand down an Actin Filament

The next question is, how do the two heads of myosin V work together to move down a filament? One model proposes that the two heads walk down a filament hand over hand with alternately leading heads (Figure 17-30a). An

EXPERIMENTAL FIGURE 17-29 Optical trap experiments measure the step size and processivity of myosins. Using an optical trap setup similar to the one described in Figure 17-28, investigators have analyzed the behavior of myosin II (top trace) and myosin V (bottom trace). As shown by the peaks in the trace, myosin II takes erratic small steps (5–15 nm), which means it binds the actin filament, moves, and then lets go. It is therefore a nonprocessive motor. By contrast, single-headed myosin V takes clear 36-nm steps one after the other, so it has a step size of 36 nm and is highly processive—that is, it does not let go of the actin filament. [Part (a) from Finer et al., 1994, *Nature* 368:113; part (b) from M. Rief et al., 2000, *Proc. Nat'l Acad. Sci. USA* 97:9482.]

alternative possibility is an inchworm model, in which the leading head takes a step, the second head is pulled up behind it, and then the leading head takes another step (Figure 17-30b). How can one distinguish between these models? In the inchworm model, each individual head takes 36-nm steps, whereas in the walking model, each takes 72-nm steps. Scientists have managed to attach a fluorescent probe to just one neck region of myosin V and watch it walk down an actin filament: it takes 72-nm steps (Figure 17-30c), and so it walks hand over hand down a filament. Why is the step size of myosin V so large? If we compare its step size of 36 nm to the structure of the actin filament, we see that it is the same as the length between helical repeats in the actin filament (see Figures 17-5b and 17-30a), so myosin V steps between equivalent

EXPERIMENTAL FIGURE 17-30 Myosin V has a step size of 36 nm, yet each head moves in 72-nm steps, so it moves hand over hand. Two models for myosin V movement down a filament have been suggested. (a) In the hand-over-hand model, one head binds an actin filament, and the other then swings around and binds a site 72 nm ahead. (b) In the inchworm model, the leading head moves 36 nm, then the lagging head moves up behind it, allowing the leading head to take another 36-nm step. (c) Two-headed myosin V labeled with a fluorescent tag on just one head appears to have a step size of 72 nm. Thus myosin V walks hand over hand. [Adapted from A. Yildiz et al., 2003, *Science* 300:2061.]

binding sites as it walks down one side of an actin filament. Myosin V has presumably evolved to take large steps the size of the helical repeat of actin and to do this very processively so that it rarely dissociates from an actin filament. These are exactly the properties one would expect for a motor designed to transport cargo along an actin filament.

KEY CONCEPTS for Section 17.5

Myosins: Actin-Based Motor Proteins

- Myosins are actin-based motors powered by ATP hydrolysis.
- Myosins have a motor head domain, a lever-arm neck domain, and a cargo-binding tail domain (see Figure 17-22).
- There are many classes of myosin, with three classes present in many eukaryotes: myosin I has a single head domain, myosin II has two heads and assembles into bipolar filaments, and myosin V has two heads but does not assemble into filaments (see Figure 17-25).
- Myosins convert ATP hydrolysis to mechanical work by amplifying a small conformational change in their head through their neck domain when the head is bound to F-actin (see Figure 17-26).
- Myosin heads take discrete steps along an actin filament, which can be small (8 nm) and nonprocessive in the case of myosin II, or large (36 nm) and processive for myosin V.

17.6 Myosin-Powered Movements

We have already discussed how myosins have head and neck domains responsible for their motor properties. We now come to the tail regions, which define the cargoes that myosins move. The function of many of the newly discovered classes of myosins found in metazoans is not yet known. In this section, we give just two examples where we have a good idea of specific myosin functions. Our first example is skeletal muscle, which is where myosin II was discovered. In muscle, many myosin II heads bundled into bipolar filaments, each with a short duty cycle, work together to bring about contraction. Similarly organized contractile machineries function in the contraction of smooth muscle and in stress fibers, as well as in the contractile ring during cytokinesis. We then turn to the myosin V class, which has a long duty cycle that allows these myosins to transport cargoes over relatively long distances without dissociating from actin filaments.

Myosin Thick Filaments and Actin Thin Filaments in Skeletal Muscle Slide Past One Another During Contraction

Muscle cells have evolved to carry out one highly specialized function: contraction. Muscle contractions must occur quickly and repetitively, and they must occur through long distances and with enough force to move large loads. A typical skeletal muscle cell is cylindrical, large (1–40 μm in length and 10–50 μm in width), and multinucleated (containing as many as 100 nuclei) (Figure 17-31a). Within each muscle cell are many **myofibrils** consisting of a regular repeating array of a specialized structure called a **sarcomere** (Figure 17-31b). A sarcomere, which is about 2 μm long in resting muscle, shortens

by about 70 percent of its length during contraction. Electron microscopy and biochemical analysis have shown that each sarcomere contains two major types of filaments: *thick filaments*, composed of myosin II, and *thin filaments*, containing actin and associated proteins (Figure 17-31c).

The thick filaments are composed of myosin II bipolar filaments, in which the heads on each half of the filament have opposite orientations (see Figure 17-22a). The thin actin filaments are assembled with their (+) ends embedded in a densely staining structure known as the *Z disk*, so that the two sets of actin filaments in a sarcomere have opposite orientations (Figure 17-32). To understand how a muscle contracts, consider the interactions between one myosin head (among the hundreds in a thick filament) and a thin (actin) filament, as diagrammed in Figure 17-26. During these cyclical interactions, also called the *cross-bridge cycle*, the hydrolysis of ATP is coupled to the movement of a myosin head toward the Z disk, which corresponds to the (+) end of the actin thin filament. Because the thick filament is bipolar, the action of the myosin heads at opposite ends of the thick filament draws the thin filaments toward the center of the thick filament and therefore toward the center of the sarcomere (see Figure 17-32). This movement shortens the sarcomere until the ends of the thick filaments abut the Z disk. Contraction of an intact muscle results from the activity of hundreds of myosin heads on a single thick filament, amplified by the hundreds of thick and thin filaments in a sarcomere and thousands of sarcomeres in a muscle fiber. We can now see why myosin II is both nonprocessive and needs to have a short duty cycle: each head pulls a short distance on the actin filament and then lets go to allow other heads to pull, and so many heads working together allow the smooth contraction of the sarcomere.

 The heart is an amazing contractile organ—it contracts without interruption about 3 million times a year, or a fifth of a billion times in a lifetime. The muscle cells of the heart contain contractile machinery very similar to that of skeletal muscle except that they are mono- and bi-nucleated cells. In each cell, the end sarcomeres insert into structures at the plasma membrane called *intercalated disks*, which link the cells into a contractile chain. Since heart muscle cells are only generated early in human life, they cannot be replaced in response to damage, such as occurs during a heart attack. Many different mutations in proteins of the heart contractile machinery give rise to *hypertrophic cardiomyopathies*—thickening of the heart wall muscle, which compromises its function. For example, many mutations have been documented in the cardiac myosin heavy-chain gene that compromise the protein's contractile function even in heterozygous individuals. In such individuals, the heart tries to compensate by hypertrophy (enlargement), often resulting in fatal heart arrhythmia (irregular beating). In addition to myosin heavy-chain defects, defects that result in cardiomyopathies have been traced to mutations in other components of the contractile machinery, including actin, myosin light chains, tropomyosin and troponin, and structural components such as titin (discussed below). ■

FIGURE 17-31 Structure of the skeletal muscle sarcomere.

(a) Skeletal muscles consist of muscle fibers made of bundles of multinucleated cells. Each cell contains a bundle of myofibrils, which consist of thousands of repeating contractile structures called sarcomeres. (b) Electron micrograph of mouse striated muscle in longitudinal section, showing one sarcomere. On either side of the Z disks are the lightly stained I bands, composed entirely of actin thin filaments. These thin filaments extend from both sides of the Z disk to interdigitate with the dark-stained myosin thick filaments in the A band. (c) Diagram of the arrangement of myosin and actin filaments in a sarcomere. [Part (b) courtesy of S. P. Dadoune.]

Skeletal Muscle Is Structured by Stabilizing and Scaffolding Proteins

The structure of the sarcomere is maintained by a number of accessory proteins (Figure 17-33). The actin filaments are stabilized on their (+) ends by *CapZ* and on their (–) ends by *tropomodulin*. A giant protein known as *nebulin* extends along the thin actin filament all the way from the Z disk to tropomodulin, to which it binds. Nebulin consists of repeating domains that bind to the actin in the filament, and it is believed that the number of actin-binding repeats, and therefore the length of nebulin, determines the length of the thin filaments. Another giant protein, called *titin* (because it is so large), has its head associated with the Z disk and extends to the middle of the thick filament, where another titin molecule extends to the subsequent Z disk. Titin is believed to be an elastic molecule that holds the thick filaments in the middle of the sarcomere and also prevents overstretching to ensure that the thick filaments remain interdigitated between the thin filaments.

Contraction of Skeletal Muscle Is Regulated by Ca^{2+} and Actin-Binding Proteins

Like many cellular processes, skeletal muscle contraction is initiated by an increase in the cytosolic Ca^{2+} concentration. As described in Chapter 11, the Ca^{2+} concentration of the cytosol is normally kept low, below $0.1 \mu\text{M}$. In skeletal muscle cells, a low cytosolic Ca^{2+} level is maintained primarily by a unique Ca^{2+} ATPase that continually pumps Ca^{2+} ions from the cytosol containing the myofibrils into the sarcoplasmic reticulum (SR), a specialized endoplasmic reticulum of the muscle cells (Figure 17-34). This activity establishes a reservoir of Ca^{2+} in the SR.

The arrival of a nerve impulse (or *action potential*; see Chapter 22) at a neuromuscular junction triggers an action potential in the muscle-cell plasma membrane (also known as the *sarcolemma*). The action potential travels down invaginations of the plasma membrane known as *transverse tubules*, which penetrate the cell to lie around each myofibril. The arrival of the action potential in the transverse tubules stimulates the opening of voltage-gated Ca^{2+} channels in the SR membrane, and the ensuing release of Ca^{2+} from the SR raises the cytosolic Ca^{2+} concentration in the myofibrils.

This elevated Ca^{2+} concentration induces a change in two accessory proteins, tropomyosin and troponin, which are bound to the actin thin filaments and normally block myosin binding. The change in position of these proteins on the actin thin filaments in turn permits the myosin-actin

FIGURE 17-32 The sliding-filament model of contraction in striated muscle. The arrangement of thick myosin and thin actin filaments in the relaxed state is shown in the top diagram. In the presence of ATP and Ca^{2+} , the myosin heads extending from the thick filaments walk toward the (+) ends of the thin filaments. Because the thin filaments are anchored at the Z disks (purple), movement of myosin pulls the actin filaments toward the center of the sarcomere, shortening its length in the contracted state, as shown in the bottom diagram.

interactions and hence contraction. This type of regulation is very rapid and is known as *thin-filament regulation*.

Tropomyosin (TM) is a ropelike molecule, about 40 nm in length, that binds to seven actin subunits in an actin filament. TM molecules are strung together head to tail, forming a continuous chain along each side of the actin thin filament (Figure 17-35a, b). Associated with each tropomyosin is *troponin* (TN), a complex of three subunits, TN-T, TN-I, and TN-C. Troponin-C is the calcium-binding subunit of troponin.

FIGURE 17-34 The sarcoplasmic reticulum regulates the level of free Ca^{2+} in myofibrils. (a) When a nerve impulse stimulates a muscle cell, the action potential is transmitted down a transverse tubule (yellow), which is continuous with the plasma membrane (sarcolemma), leading to release of Ca^{2+} from the adjacent sarcoplasmic reticulum

FIGURE 17-33 Accessory proteins found in skeletal muscle. To stabilize the actin filaments, CapZ caps the (+) end of the thin filaments at the Z disk, whereas tropomodulin caps the (-) end. The giant protein titin extends through the thick filaments and attaches to the Z disk. Nebulin binds actin subunits and determines the length of the thin filament.

TN-C controls the position of TM on the surface of an actin filament through the TN-I and TN-T subunits.

Under the control of Ca^{2+} and TN, TM can occupy two positions on a thin filament—switching from a state of muscle relaxation to contraction. In the absence of Ca^{2+} (the relaxed state), TM blocks myosin's interaction with F-actin and the muscle is relaxed. Binding of Ca^{2+} ions to TN-C triggers movement of TM to a new site on the filament, thereby exposing the myosin-binding sites on actin (see Figure 17-35b). Thus, at Ca^{2+} concentrations greater than $1 \mu\text{M}$, the inhibition exerted by the TM-TN complex is relieved and contraction occurs. The Ca^{2+} -dependent cycling between

relaxation and contraction states in skeletal muscle is summarized in Figure 17-35c.

Actin and Myosin II Form Contractile Bundles in Nonmuscle Cells

In skeletal muscle, actin thin filaments and myosin II thick filaments assemble into contractile structures. Nonmuscle cells contain several types of related contractile bundles composed of actin and myosin II filaments, which are similar to skeletal muscle fibers but much less organized. Moreover, they lack the troponin regulatory system and are instead regulated by myosin phosphorylation, as we will discuss later.

In epithelial cells, contractile bundles are most commonly found as an *adherens belt*, also known as the circumferential belt, which encircles the inner surface of the cell at the level of the adherens junction (see Figure 17-4a) and are important in maintaining the integrity of the epithelium (discussed in Chapter 20). Stress fibers, which are seen along the lower surfaces of cells cultured on artificial (glass or plastic) surfaces or in extracellular matrices, are a second type of contractile bundle (see Figure 17-4a, c) important in cell adhesion, especially on deformable substrates. The ends of stress fibers terminate at integrin-containing focal adhesions, special structures that attach a cell to the underlying substratum (see Figure 17-41 and Chapter 20). Circumferential belts and stress fibers contain several proteins found in the contractile apparatus of smooth muscle and exhibit some organizational features resembling

those of muscle sarcomeres. A third type of contractile bundle, referred to as a contractile ring, is a transient structure that assembles at the equator of a dividing cell, encircling the cell midway between the poles of the mitotic spindle (Figure 17-36a). As the ring contracts, pulling the plasma membrane in, the cytoplasm is divided and eventually pinched into two parts in a process known as *cytokinesis*, giving rise to two daughter cells. Dividing cells stained with antibodies against myosin I and myosin II show that myosin II is localized to the contractile ring, whereas myosin I is at the distal regions, where it links the actin cortex to the plasma membrane (Figure 17-36b). Cells deleted for the gene encoding the heavy chain of myosin II are unable to undergo cytokinesis, thereby establishing a role for myosin II in cell division. Instead, these cells form a multinucleated syncytium because cytokinesis, but not nuclear division, is inhibited.

Myosin-Dependent Mechanisms Regulate Contraction in Smooth Muscle and Nonmuscle Cells

Smooth muscle is a specialized tissue composed of contractile cells that is found in many internal organs. For example, smooth muscle surrounds blood vessels to regulate blood pressure, surrounds the intestine to move food through the gut, and restricts airway passages in the lung. Smooth muscle cells contain large, loosely aligned contractile bundles that

EXPERIMENTAL FIGURE 17-36 Fluorescent antibodies reveal the localization of myosin I and myosin II during cytokinesis.

(a) Diagram of a cell going through cytokinesis, showing the mitotic spindle (microtubules green, chromosomes blue) and the contractile ring with actin filaments (red). (b) Fluorescence micrograph of a *Dictyostelium ameba* during cytokinesis reveals that myosin II (orange)

is concentrated in the contractile ring, also known as the cleavage furrow, whereas myosin I (green) is localized at the poles of the cell. The cell was stained with antibodies specific for myosin I and myosin II, with each antibody preparation linked to a different fluorescent dye. [Courtesy of Y. Fukui.]

resemble the contractile bundles in epithelial cells. The contractile apparatus of smooth muscle and its regulation constitute a valuable model for understanding how myosin activity is regulated in a nonmuscle cell. As we have just seen, skeletal muscle contraction is regulated by the tropomyosin-troponin complex bound to the actin thin filament switching between the contraction-inducing state in the presence of Ca^{2+} and the relaxed state in its absence. In contrast, smooth muscle contraction is regulated by the cycling of myosin II between on and off states. Myosin II cycling, and thus contraction of smooth muscle and nonmuscle cells, is regulated in response to many extracellular signaling molecules.

Contraction of vertebrate smooth muscle is regulated primarily by a pathway in which the *myosin regulatory light chain (LC)* associated with the myosin II neck domain (see Figure 17-22b) undergoes phosphorylation and dephosphorylation. When the regulatory light chain is not phosphorylated, the smooth muscle myosin II adopts a folded conformation and its ATPase cycle is inactive. When the regulatory LC is phosphorylated by the enzyme *myosin LC kinase*, whose activity is regulated by the level of cytosolic free Ca^{2+} , the myosin II unfolds and assembles into active bipolar filaments and becomes active to induce contraction (Figure 17-37). The Ca^{2+} -dependent regulation of myosin LC kinase activity is mediated through the Ca^{2+} -binding protein calmodulin (see Figure 3-31). Calcium first binds to calmodulin, which induces a conformational change in the protein, and the Ca^{2+} /calmodulin complex then binds to myosin LC kinase and activates it. When the Ca^{2+} returns to its resting level, myosin LC kinase becomes inactive and myosin light-chain phosphatase removes the phosphates to allow the system to return to its relaxed state. This mode of regulation relies on the diffusion of Ca^{2+} over greater distances than in sarcomeres and on the action of protein kinases, so contraction

is much slower in smooth muscle than in skeletal muscle. Because this regulation involves myosin, it is known as *thick-filament regulation*.

The role of activated myosin LC kinase can be demonstrated by microinjecting a kinase inhibitor into smooth muscle cells. Even though the inhibitor does not block the rise in the cytosolic Ca^{2+} level that occurs following stimulation of the cell, injected cells cannot contract.

Unlike skeletal muscle, which is stimulated to contract solely by nerve impulses, smooth muscle cells and nonmuscle cells are regulated by many types of external signals. For example, norepinephrine, angiotensin, endothelin, histamine, and other signaling molecules can modulate or induce the contraction of smooth muscle, or elicit changes in the shape and adhesion of nonmuscle cells by triggering various signal-transduction pathways. Some of these pathways lead to an increase in the cytosolic Ca^{2+} level; as previously described, this increase can stimulate myosin activity by activating myosin LC kinase (see Figure 17-37). As we will discuss below, other pathways activate *Rho kinase*, which is also able to activate myosin activity by phosphorylating the regulatory light chain, although in a Ca^{2+} -independent manner.

Myosin-V-Bound Vesicles Are Carried Along Actin Filaments

In contrast to the contractile functions of myosin II filaments, the myosin V family of proteins are the most processive myosin motors known and transport cargo down actin filaments. In the next chapter we discuss how they can work together with microtubule motors to bring about transport of organelles. Although not a lot is known about their functions in mammalian cells, myosin V motors are not unimportant: defects in a

FIGURE 17-37 Myosin phosphorylation mechanism for regulating smooth muscle contraction. In vertebrate smooth muscle, phosphorylation of the myosin regulatory light chain (LC) activates contraction. At Ca^{2+} concentrations $< 10^{-6}$ M, the regulatory light chain is not phosphorylated, and the myosin adopts a folded conformation. When the Ca^{2+} level rises, it binds calmodulin (CaM), which undergoes a conformational change (CaM*). The CaM*- Ca^{2+} complex binds and activates myosin light-chain kinase (MLC kinase), which then phosphorylates the myosin LC. This phosphorylation event unfolds the myosin, which is now active and can assemble into bipolar filaments to participate in contraction. When the Ca^{2+} levels drop, the myosin LC is dephosphorylated by myosin light-chain (MLC) phosphatase, which is not dependent on Ca^{2+} for activity, causing muscle relaxation.

specific myosin V protein can cause severe diseases, such as seizures (see Figure 17-24).

Much more is known about myosin V motors in more experimentally accessible and simpler systems such as the budding yeast. This well-studied organism grows by budding, which requires its secretory machinery to target newly synthesized material to the growing bud (Figure 17-38a). Myosin V transports secretory vesicles along actin filaments at $3 \mu\text{m/s}$ into the bud. However, this is not the only function of myosin V proteins in yeast. At a later stage of the cell cycle, all the organelles have to be distributed between the mother and daughter cells. Remarkably, myosin Vs in yeast

OVERVIEW ANIMATION: Movement of Multiple Cargoes by Myosin V in Yeast

FIGURE 17-38 Cargo movement by myosin Vs in budding yeast.

(a) The yeast *Saccharomyces cerevisiae* (used in making bread, beer, and wine) grows by budding. Secretory vesicles are transported into the bud, which swells to about the size of the mother cell. The cells then go through cytokinesis to form two daughter cells, and each divides again. (b) Diagram of a medium-sized bud showing how myosin Vs transport secretory vesicles (SV) down actin cables nucleated by formins (purple) located at the bud tip and bud neck. Myosins Vs are also used to segregate organelles, such as the vacuole (the yeast equivalent of a lysosome), peroxisomes, endoplasmic reticulum (ER), *trans*-Golgi network (TGN), and even selected mRNAs into the bud. Myosin V also binds the end of cytoplasmic microtubules (green) to orient the nucleus in preparation for mitosis. [Adapted from D. Pruyne et al., 2004, *Ann. Rev. Cell Biol.* 20:559.]

provide the transport system for segregation of many organelles, including peroxisomes, lysosomes (also known as vacuoles), endoplasmic reticulum, the *trans*-Golgi network, and even transport the ends of microtubules and some specific messenger RNAs into the bud (Figure 17-38b). Whereas budding yeast uses myosin V and polarized actin filaments in the transport of many organelles, animal cells, which are much larger, employ microtubules and their motors to transport many of these organelles over relatively long distances. We discuss these transport mechanisms in the next chapter.

Perhaps the most dramatic use of myosin Vs is seen in the giant green algae, such as *Nitella* and *Chara*. In these large cells, which can be 2 cm in length, cytosol flows rapidly, at a rate approaching 4.5 mm/min, in an endless loop around the inner circumference of the cell (Figure 17-39). This *cytoplasmic streaming* is a principal mechanism for distributing cellular metabolites, especially in large cells such as plant cells and amoebas.

Close inspection of objects caught in the flowing cytosol, such as the endoplasmic reticulum (ER) and other membrane-bounded vesicles, shows that the velocity of streaming increases

FIGURE 17-39 Cytoplasmic streaming in cylindrical giant algae.

(a) Cells of *Nitella*, a freshwater alga commonly found in ponds in the summer. The cytoplasmic movement, described below, is amazing and can readily be observed with a simple microscope, so go find some *Nitella* (or related alga) and watch this wonderful phenomenon! (b) The center of a *Nitella* cell is filled with a single large water-filled vacuole, which is surrounded by a layer of moving cytoplasm (blue arrows). A nonmoving layer of cortical cytoplasm filled with chloroplasts lies just under the plasma membrane (enlarged in bottom figure). On the inner

side of this layer are bundles of stationary actin filaments (red), all oriented with the same polarity. A motor protein (blue), a plant myosin V, carries parts of the endoplasmic reticulum (ER) along the actin filaments. The movement of the ER network propels the entire viscous cytoplasm, including organelles that are enmeshed in the ER network. (c) Electron micrograph of the cortical cytoplasm showing a large vesicle connected to an underlying bundle of actin filaments. [Part (a) from James C. French; part (c) from B. Kachar.]

from the cell center (zero velocity) to the cell periphery. This gradient in the rate of flow is most easily explained if the motor generating the flow lies at the membrane. In electron micrographs, bundles of actin filaments can be seen aligned along the length of the cell, lying above stationary chloroplasts located adjacent to the membrane. The bulk cytosol is propelled by myosin V (also known as myosin XI in plants) attached to parts of the ER adjacent to the actin filaments. The flow rate of the cytosol in *Nitella* is about 15 times as fast as the movement produced by any other known myosin.

KEY CONCEPTS of Section 17.6

Myosin-Powered Movements

- In skeletal muscle, contractile myofibrils are composed of thousands of repeating units called sarcomeres. Each sarcomere consists of two interdigitating filament types: myosin thick filaments and actin thin filaments (see Figure 17-31).
- Skeletal muscle contraction involves the ATP-dependent sliding of myosin thick filaments along actin thin filaments to shorten the sarcomere and hence the myofibril (see Figure 17-32).
- The ends of the actin thin filaments in skeletal muscle are stabilized by CapZ at the (+) end and by tropomodulin at the (–) end. Two large proteins, nebulin associated with the thin filaments and titin with the thick filaments, also contribute to skeletal muscle organization.
- Skeletal muscle contraction is subject to thin-filament regulation. At low levels of free Ca^{2+} , the muscle is relaxed and tropomyosin blocks the interaction of myosin and F-actin. At elevated levels of free Ca^{2+} , the troponin complex associated with tropomyosin binds Ca^{2+} and moves the tropomyosin to uncover the myosin-binding sites on actin, allowing contraction (see Figure 17-35).
- Smooth and nonmuscle cells have contractile bundles of actin and myosin filaments, with a similar organization as skeletal muscle but less well ordered.
- Contractile bundles are subject to thick-filament regulation. A myosin light chain is phosphorylated by myosin light-chain kinase, which activates myosin and hence induces contraction. The myosin light-chain kinase is activated by binding Ca^{2+} -calmodulin when the free Ca^{2+} concentration rises (see Figure 17-37).
- Myosin V transports cargo by walking processively along actin filaments.

17.7 Cell Migration: Mechanism, Signaling, and Chemotaxis

We have now examined the different mechanisms used by cells to create movement—from the assembly of actin filaments and the formation of actin-filament bundles and networks to the contraction of bundles of actin and myosin and the transport of

organelles by myosin molecules along actin filaments. Some of these same mechanisms constitute the major processes whereby cells generate the forces needed to migrate. *Cell migration* results from the coordination of motions generated in different parts of a cell, integrated with a directed endocytic cycle.

The study of cell migration is important to many fields of biology and medicine. For example, an essential feature of animal development is the migration of specific cells along predetermined paths. Epithelial cells in an adult animal migrate to heal a wound, and white blood cells migrate to sites of infection. Less obvious are the continual slow migration of intestinal epithelial cells along the villi in the intestine and the slow but constant migration of endothelial cells that line the blood vessels. The inappropriate migration of cancer cells after breaking away from their normal tissue results in metastasis.

Cell migration is initiated by the formation of a large, broad membrane protrusion at the leading edge of a cell. Video microscopy reveals that a major feature of this movement is the polymerization of actin at the membrane. Actin filaments at the leading edge are rapidly cross-linked into bundles and networks in a protruding region, called a *lamellipodium* in vertebrate cells. In some cases, slender, fingerlike membrane projections, called *filopodia*, also extend from the leading edge. These structures form stable contacts with the underlying surface (such as the extracellular matrix) that the cell moves across. In this section, we take a closer look at how cells coordinate various microfilament-based processes with endocytosis to move across a surface. We also consider the role of signaling pathways in coordinating and integrating the actions of the cytoskeleton, a major focus of current research.

Cell Migration Coordinates Force Generation with Cell Adhesion and Membrane Recycling

A moving fibroblast (connective tissue cell) displays a characteristic sequence of events—initial extension of a membrane protrusion, attachment to the substratum, forward flow of cytosol, and retraction of the rear of the cell (Figure 17-40). These events occur in an ordered pattern in a slowly moving cell such as a fibroblast, but in rapidly moving cells, such as macrophages, all of them are occurring simultaneously in a coordinated manner. We first consider the role of the actin cytoskeleton, and then the involvement of the endocytic cycle.

Membrane Extension The network of actin filaments at the leading edge is a type of cellular engine that pushes the membrane forward in a manner very similar to the propulsion of *Listeria* by actin polymerization (Figure 17-41d; for *Listeria*, see Figure 17-17c). Thus at the membrane of the leading edge, actin is nucleated by the activated Arp2/3 complex and filaments are elongated by assembly onto (+) ends adjacent to the plasma membrane. As the actin meshwork is fixed with respect to the substratum, the front membrane is pushed out as the filaments elongate. This is very similar to *Listeria*, which “rides” on the polymerizing actin tail, which is also fixed within the cytoplasm. Actin turnover, and thus treadmilling, is mediated, as it is in the comet tails of *Listeria*, by the action of profilin and cofilin (see Figure 17-41d).

VIDEO: Mechanism of Fish Keratinocyte Migration
VIDEO: Actin Filaments in the Lamellipodium of a Fish Keratinocyte

FIGURE 17-40 Steps in cell movement. Movement begins with the extension of one or more lamellipodia from the leading edge of the cell **1**; some lamellipodia adhere to the substratum by focal adhesions **2**. Then the bulk of the cytoplasm in the cell body flows forward due to contraction at the rear of the cell **3**. The trailing edge of the cell remains attached to the substratum until the tail eventually detaches and retracts into the cell body. During this cytoskeleton-based cycle, the endocytic cycle internalizes membrane and integrins at the rear of the cell and transports them to the front of the cell (arrows) for reuse in making new adhesions **4**.

Cell-Substrate Adhesions When the membrane has been extended and the cytoskeleton has been assembled, the plasma membrane becomes firmly attached to the substratum. Time-lapse microscopy shows that actin bundles in the leading edge become anchored to structures known as *focal adhesions* (Figure 17-41c). The attachment serves two purposes: it prevents the leading lamella from retracting, and it attaches the cell to the substratum, allowing the cell to move forward. Given the importance of focal adhesions and their regulation during cell locomotion, it is not surprising that they have been found to be very rich in molecules involved in signal-transduction pathways. Focal adhesions are discussed in more detail in Chapter 20, when we discuss cell-matrix interactions.

The cell-adhesion molecules that mediate most cell-matrix interactions are membrane proteins called *integrins*. These proteins have an external domain that binds to specific components of the extracellular matrix, such as fibronectin and collagen, and a cytoplasmic domain that links them to the actin cytoskeleton (see Figure 17-41c and Chapter 20). The cell makes attachments at the front, and as the cell migrates forward, the adhesions eventually assume positions toward the back.

Cell-Body Translocation After the forward attachments have been made, the bulk contents of the cell body are translocated forward (see Figure 17-40, step **3**). It is believed that the nucleus and the other organelles embedded in the cytoskeleton are moved forward by myosin II-dependent cortical contraction in the rear part of the cell, like squeezing the lower half of a tube of toothpaste. Consistent with this model, myosin II is localized to the rear cell cortex.

Breaking Cell Attachments Finally, in the last step of movement (de-adhesion), the focal adhesions at the rear of the cell are broken, the integrins recycled, and the freed tail brought forward. In the light microscope, the tail is seen to “snap” loose from its connections—perhaps by the contraction of stress fibers in the tail or by elastic tension—and it sometimes leaves a little bit of its membrane behind, still firmly attached to the substratum.

The ability of a cell to move corresponds to a balance between the mechanical forces generated by the cytoskeleton

and the resisting forces generated by cell adhesions. Cells cannot move if they are either too strongly attached or not attached to a surface. This relationship can be demonstrated by measuring the rate of movement in cells that express varying levels of integrins. Such measurements show that the fastest migration occurs at an intermediate level of adhesion, with the rate of movement falling off at high and low levels of adhesion. Cell locomotion thus results from traction forces exerted by the cell on the underlying substratum.

Recycling Membrane and Integrins by Endocytosis The dynamic changes in the actin cytoskeleton alone are not sufficient to drive cell migration; it is also dependent on endocytic recycling of membranes. The membrane needed during lamellipodium extension is provided from internal endosomes following their exocytosis. Adhesion molecules in focal adhesions at the rear of the cell are internalized from disassembling focal contacts and transported by an endocytic cycle to the front to make new substrate attachments (Figure 17-40, step **4**). This cycle of adhesion molecules in a migrating cell resembles the way a tank uses its treads to move forward. This movement of membrane internally through the cell also generates a rearwards membrane flow across the surface of the cell. Indeed, this type of flow may contribute to cell locomotion, as it has recently been found that white blood cells can move in a liquid (“swim”) in the absence of attachment to a substrate.

FIGURE 17-41 Actin-based structures involved in cell locomotion. (a) Localization of actin in a fibroblast expressing GFP-actin. (b) Diagram of the classes of microfilaments involved in cell migration. The meshwork of actin filaments in the leading edge advances the cell forward. Contractile fibers in the cell cortex squeeze the cell body forward, and stress fibers terminating in focal adhesions also pull the bulk of the cell body up as the rear adhesions are released.

(c) The structure of focal adhesions involves the attachment of the ends of stress fibers through integrins to the underlying extracellular matrix. Focal adhesions also contain many signaling molecules important for cell locomotion. (d) The dynamic actin meshwork in the leading edge is nucleated by the Arp2/3 complex and employs the same set of factors that control assembly and disassembly of actin filaments in the *Listeria* tail (see Figure 17-17). The Small GTP-Binding Proteins Cdc42, Rac, and Rho Control Actin Organization

A striking feature of a moving cell is its polarity: a cell has a front and a back. When a cell makes a turn, a new leading edge forms in the new direction. If these extensions formed in all directions at once, the cell would be unable to pick a new direction of movement. To sustain movement in a particular direction, a cell requires signals to coordinate events at the front of the cell with events at the back and, indeed, signals to tell the cell where its front is. Understanding how this coordination occurs emerged from studies with growth factors.

Growth factors, such as epidermal growth factor (EGF) and platelet-derived growth factor (PDGF), bind to specific

cell-surface receptors (Chapter 16) and stimulate cells to move and then to divide. For example, in a wound, blood platelets become activated by being exposed to collagen in the extracellular matrix at the wound edge, which helps the blood to clot. Activated platelets also secrete PDGF to attract fibroblasts and epithelial cells to enter the wound and repair it. It is possible to watch part of this process in vitro. If you grow cells in a culture dish and, after starving them of growth factors, you add some fresh growth factor, within a minute or two the cells respond by forming membrane ruffles. Membrane ruffles are very similar to the lamellipodia of migrating cells: they are a result of activation of the machinery that controls exocytosis of endosomes coupled with actin assembly.

Scientists knew that growth factors bind to very specific receptors on the cell surface and induce a signal-transduction pathway on the inner surface of the plasma membrane (Chapter 15), but how that linked up to the actin machinery was mysterious. Research then revealed that the signal-transduction pathway activates *Rac*, a member of the small GTPase superfamily of Ras-related proteins (Chapter 15). *Rac* is one member of a family of proteins that regulate microfilament organization; two others are *Cdc42* and *Rho*. Unfortunately, due to the history of their discovery, this family of proteins also has been collectively named “Rho proteins,” of which *Cdc42*, *Rac*, and *Rho* are members. To understand how these proteins work, we first have to recall the way small GTP-binding proteins function.

Like all small GTPases of the Ras superfamily, *Cdc42*, *Rac*, and *Rho* act as molecular switches, inactive in the GDP-bound state and active in the GTP-bound state (Figure 17-42). In their GDP-bound state, they exist free in the cytoplasm in an inactive form bound to a protein known as guanine nucleotide dissociation inhibitor (GDI). Growth factors can bind and activate their receptors to turn on specific membrane-bound regulatory proteins, guanine nucleotide exchange factors (GEFs), which activate Rho proteins at the membrane by releasing them from GDI and catalyzing the exchange of GDP for GTP. The GTP-bound active Rho protein associates with the plasma membrane, where it binds *effector proteins* to initiate the biological response. The small GTPase remains active until the GTP is hydrolyzed to GDP, which is stimulated by specific GTPase-activating proteins (GAPs). An important approach to unraveling the functions of Rho proteins has been

to introduce into cells mutant proteins that are locked either in the active—Rho-GTP—state or in the inactive—Rho-GDP—state. A mutant small GTPase that is locked in the active state is said to be a *dominant-active* protein. Such a dominant-active protein binds the effector molecules constitutively, and one can then assess the biological outcomes. Alternatively, one can introduce a different mutant that is *dominant-negative*, which binds and thereby inhibits the relevant GEF protein. Thus introduction of a dominant-negative protein interferes with the signal-transduction pathway, so one can now assess what processes are blocked.

Cdc42, *Rac*, and *Rho* were implicated in regulation of microfilament organizations because introduction of dominant-active mutants had dramatic effects on the actin cytoskeleton, even in the absence of growth factors. It was discovered that dominant-active *Cdc42* resulted in the appearance of filopodia, dominant-active *Rac* resulted in the appearance of membrane ruffles, and dominant-active *Rho* resulted in the formation of stress fibers that then contracted (Figure 17-43). How can one tell if dominant-active *Rac* and growth-factor stimulation, both of which stimulate membrane ruffle formation, operate in the

FIGURE 17-42 Regulation of the Rho family of small GTPases. The Rho family of small GTPases are molecular switches regulated by accessory proteins. Rho proteins exist in the Rho-GDP bound form complexed with a protein known as GDI (guanine nucleotide dissociation inhibitor), which retains them in an inactive state in the cytosol. Membrane-bound signaling pathways bring Rho proteins to the membrane and, through the action of a GEF (guanine nucleotide exchange factor), exchange the GDP for GTP, thus activating them. Membrane-bound activated Rho-GTP can then bind effector proteins that cause changes in the actin cytoskeleton. The Rho protein remains in the active Rho-GTP state until acted on by a GAP (GTPase-activating protein), which returns it to the cytoplasm. [Adapted from S. Etienne-Manneville and A. Hall, 2002, *Nature* 420:629.]

EXPERIMENTAL FIGURE 17-43 Dominant-active Rac, Rho, and Cdc42 induce different actin-containing structures. To look at the effects of constitutively active Rac, Rho, and Cdc42, growth-factor-starved fibroblasts were microinjected with plasmids to express dominant-active versions of the three proteins. The cells were then treated with fluorescent phalloidin, which stains filamentous actin. Dominant-active Rac induces the formation of peripheral membrane ruffles, whereas dominant-active Rho induces abundant contractile stress fibers and dominant active Cdc42 induces filopodia. [From A. Hall, 1998, *Science* 279:509.]

FIGURE 17-44 Summary of signal-induced changes in the actin cytoskeleton. Specific signals, such as growth factors and lysophosphatidic acid (LPA), are detected by cell-surface receptors. Detection leads to the activation of the small GTP-binding proteins, which then interact with effectors to bring about cytoskeletal changes as indicated.

same signal-transduction pathway? If growth-factor stimulation leads to Rac activation, introduction of a dominant-negative Rac protein into a cell should block the ability of a growth factor to induce membrane ruffling. This is precisely what is found. Using this and many other biochemical strategies, scientists have identified signaling pathways involving Cdc42, Rac, and Rho (Figure 17-44).

Some of the pathways that these proteins regulate contain proteins we are familiar with. Activation of Cdc42 stimulates actin assembly by Arp2/3 through activation of WASp, a nucleation-promoting-factor (NPF) protein (see Figure 17-16), resulting in the formation of filopodia. Activation of Rac also induces Arp2/3, mediated by the WAVE complex, leading to the assembly of branched actin filaments in the leading edge. Activation of Rho has at least two effects. First, it can activate a formin for unbranched actin filament assembly. Second, through activation of Rho kinase, it can phosphorylate the myosin light chain to activate nonmuscle myosin II and also inhibit light-chain dephosphorylation by phosphorylating myosin light-chain phosphatase to inhibit its activity. Both actions of Rho kinase lead to a higher level of myosin light-chain phosphorylation and therefore higher myosin activity and contraction. The three Rho proteins, Cdc42, Rac, and Rho, are also linked by activation and inhibition pathways, as shown in Figure 17-44.

Cell Migration Involves the Coordinate Regulation of Cdc42, Rac, and Rho

How does each of these small GTP-binding proteins contribute to the regulation of cell migration? To answer this question, researchers developed an *in vitro* wound-healing

assay (Figure 17-45a). Cells in culture are grown in a petri dish with growth factors, allowing them to grow until they are confluent and form a tight monolayer, at which point they stop dividing. The cell monolayer is then scratched with a needle to remove a swath of cells to generate a “wound” containing a free edge of cells. The cells on the edge sense the loss of their neighbors and, in response to components of the extracellular matrix now exposed on the dish surface, move to fill up the empty wound area (Figure 17-45b). To do this, they orient themselves toward the free area, first putting out a lamellipodium and then moving in that direction. In this way one can study the induction of directed cell migration *in vitro*.

Using this system, researchers have introduced dominant-negative Rac into cells on the wound edge to see how it affects the ability of the cells to migrate and fill the wound. Since Rac is needed for activation of the Arp2/3 complex to form the lamellipodium, it is not surprising that the cells fail to form this structure and do not migrate, and so the wound does not close (Figure 17-45c). A very interesting result is obtained when dominant-negative Cdc42 is introduced into the cells at the wound edge: they can form a leading edge but do not orient in the correct direction—in fact, they try to migrate in random directions. This suggests that Cdc42 is critical for regulating the overall polarity of the cell. Studies from yeast (where Cdc42 was first described), wounded-cell monolayers, epithelial cells, and neurons reveal that Cdc42 is a master regulator of polarity in many different systems. Part of this regulation in animals involves Cdc42 binding to its effector, Par6, a polarity protein that functions in nematodes (where it was first discovered), neurons, and epithelial cells. We explore these polarity pathways in more detail in Chapter 21.

EXPERIMENTAL FIGURE 17-45 The wounded-cell monolayer assay can be used to dissect signaling pathways in directed cell movement. (a) A confluent layer of cells is scratched to remove a swath of about three cells wide to generate a free cell border. The cells detect the free space and newly exposed extracellular matrix and, over a period of hours, fill the area. (b) Localization of actin in a wounded monolayer 5 minutes and 3 hours after scratching; the cells have migrated into the wounded area. (c) Effect of introducing dominant-negative Cdc42, Rac, and Rho into cells at the wound edge; all affect wound closure. [Parts (b) and (c) from C. D. Nobes and A. Hall, 1999, *J. Cell Biol.* 144:1235.]

Studies such as these suggest a general model of how cell migration is controlled (Figure 17-46). Signals from the environment are transmitted to Cdc42, which orients the cell. The oriented cell has high Rac activity at the front, to induce the formation of the leading edge; Rho activity is high in the rear, to assemble contractile structures and activate the myosin-II-based contractile machinery. It is important to notice that different regions of the cell can have different levels of active Cdc42, Rac, or Rho, so these regulators are controlled locally within the cell. Part of this spatial regula-

tion occurs because some small G proteins can work antagonistically. For example, active Rho can stimulate pathways that lead to the inactivation of Rac. This might help ensure that no leading-edge structures form at the rear of the cell.

Migrating Cells Are Steered by Chemotactic Molecules

Under certain conditions, extracellular chemical cues guide the locomotion of a cell in a particular direction. In some cases, the movement is guided by insoluble molecules in the underlying substratum, as in the wound-healing assay described above. In other cases, the cell senses soluble molecules and follows them, along a concentration gradient, to their source—a process known as **chemotaxis**. For example, leukocytes (white blood cells) are guided toward an infection by a tripeptide secreted by many bacterial cells (Figure 17-47a). In another example, during the development of skeletal muscle, a secreted protein signal called *scatter factor* guides the migration of myoblasts to the proper locations in limb buds. One of the best-studied examples of chemotaxis is the migration of *Dictyostelium* amoebae during their starvation response. When these soil amoebae are stressed, they begin to secrete cAMP, which is an extracellular chemotactic agent in this organism. Other *Dictyostelium* cells move up the cAMP concentration gradient toward its source (see Figure 17-47a). Thus the amoebae move toward each other, aggregate into a migratory slug, and then differentiate into a fruiting body in which starvation-resistant spores are formed.

Despite the variety of different chemotactic molecules—sugars, peptides, cell metabolites, cell-wall or membrane lipids—they all work through a common and familiar mechanism: binding to cell-surface receptors, activation of intracellular signaling pathways, and remodeling of the cytoskeleton through the activation or inhibition of various actin-binding

FIGURE 17-46 Contribution of Cdc42, Rac, and Rho to cell movement. The overall polarity of a migrating cell is controlled by Cdc42, which is activated at the front of a cell. Cdc42 activation leads to active Rac in the front of the cell, which generates the leading edge, and active Rho at the back of the cell, which causes myosin II activation and contraction. Active Rho inhibits Rac activation, ensuring the asymmetry of the two active G-proteins.

EXPERIMENTAL FIGURE 17-47 Chemotaxis involves elevated levels of signaling phosphoinositides, which signal to the actin cytoskeleton. (a) *Dictyostelium* cells migrate toward a pipet of cAMP (left), and human neutrophils (a type of leukocyte) migrate toward a pipet of fMLP (formylated Met-Leu-Phe), a chemotactic peptide produced by bacteria (right). In the lower two panels are individual chemotaxing *Dictyostelium* and neutrophil cells that look remarkably similar, despite about 800 million years of evolution separating them. (b) Summary of results of studies exploring the localization of

components of signaling pathways (green) in *Dictyostelium* cells undergoing chemotaxis toward cAMP. Also shown are the localization of actin and myosin (red). (c) The enzyme PI-3 kinase, which generates PI(3,4,5)P₃, is enriched at the front of chemotaxing cells, whereas PTEN, the phosphatase that hydrolyses PI(3,4,5)P₃, is enriched at the back. These distributions result in elevated PI(3,4,5)P₃ at the front of the cells, which signals the polarity for movement. [Part (a) from C. Parent, 2004, *Curr. Opin. Cell Biol.* 16:4; part (c) from M. Iijima et al., 2002, *Dev. Cell* 3:469.]

proteins. What is quite amazing is that just a 2 percent difference in the concentration of chemotactic molecules between the front and back of the cell is sufficient to induce directed cell migration. Equally amazing is the finding that the internal signal-transduction pathways used in chemotaxis have been conserved between *Dictyostelium* amoebas and human leukocytes despite almost a billion years of evolution.

Chemotactic Gradients Induce Altered Phosphoinositide Levels Between the Front and Back of a Cell

To investigate how *Dictyostelium* amoebas sense a chemotactic gradient, investigators have studied the cell-surface receptors for extracellular cAMP and downstream signaling pathways in the expectation that these must somehow sense the concentration gradient. Before we discuss the details, let's consider how such a system might work. If a cell can sense a 2 percent difference in concentration across its length, it is unlikely that simply activating actin assembly 2 percent more at the front than at the back could lead to directed movement. Rather, there must be some mechanism that amplifies this small external signal difference into a large internal biochemical difference. One way to do this would be for the cell to subtract the average signal from the front and back and only respond to a *difference in signal*. It is believed that this is how the system works. To try to understand this mechanism, investigators have looked at the concentration of active components of the signaling pathway to see where the amplification occurs.

Micrographs of cAMP receptors tagged with green fluorescent protein (GFP) show that the receptors are distributed

uniformly on the surface of an amoeba cell (Figure 17-47b); therefore an internal gradient must be established by another component of the signaling pathway. Because cAMP receptors signal through trimeric G proteins (Chapter 16), a subunit of the trimeric G protein and other downstream signaling proteins were tagged with GFP to look at their distributions. Fluorescence micrographs show that the concentration of trimeric G proteins is also rather uniform. Downstream of the trimeric G proteins is PI-3 kinase, an enzyme that phosphorylates membrane-bound inositol phospholipids (phosphoinositides), such as PI(4,5)P₂, creating the signaling lipid PI(3,4,5)P₃ (see Figure 16-25). Remarkably, the enzyme PI-3 kinase is highly enriched at the front of a migrating cell, as are its products. PTEN, the phosphatase that dephosphorylates the signaling lipid PI(3,4,5)P₃ back to PI(4,5)P₂, is enriched in the tail of the migrating cell (Figure 17-47b, c). This asymmetry is believed to be established in the following way. Prior to the cell's exposure to a cAMP gradient, the phosphatase PTEN is associated uniformly with the plasma membrane. When a cell "sees" a gradient, PI 3-kinase is activated a bit more at the front than the back. This results in slightly higher levels of the signaling phospholipid at the front. The association of the phosphatase PTEN with the membrane is very sensitive to the level of PI(3,4,5)P₃, so it is preferentially depleted from the front. Since it is less effective at dephosphorylating the PI(3,4,5)P₃ at the front and more effective at dephosphorylating PI(3,4,5)P₃ at the rear, a strong asymmetry of PI(3,4,5)P₃ results. Thus the phosphatase PTEN contributes to the background subtraction necessary for a cell to sense a shallow gradient of chemoattractant.

The difference in local $\text{PI}(3,4,5)\text{P}_3$ concentration now signals to the actin cytoskeleton to assemble a leading edge at the front and contraction at the rear (Figure 17-47b), and the cell is on its way to the source of chemoattractant. A very similar mechanism has been implicated in the chemotaxis of leukocytes. This cell polarization is not stable in the absence of the chemotactic gradient, so if the gradient changes, as might happen with a leukocyte chasing a moving bacterium, the cell will also change its direction and follow the gradient to its source.

KEY CONCEPTS of Section 17.7

Cell Migration: Mechanism, Signaling, and Chemotaxis

- Cell migration involves the extension of an actin-rich leading edge at the front of the cell, the formation of adhesive contacts that move backward with respect to the cell, and their subsequent release, combined with rear contraction to push the cell forward (see Figure 17-40).
- Cell migration also involves a directed endocytic cycle, taking membrane and adhesion molecules from the rear of the cell and inserting them at the front.
- The assembly and function of actin filaments is controlled by signaling pathways through small GTP-binding proteins of the Rho family. Cdc42 regulates overall polarity and the formation of filopodia, Rac regulates actin meshwork formation through the Arp2/3 complex, and Rho regulates both actin filament formation by formins as well as contraction through regulation of myosin II (see Figure 17-44).
- Chemotaxis, the directed movement toward an attractant, involves signaling pathways that establish differences in phosphoinositides between the front and rear of the cell, which in turn regulate the actin cytoskeleton and direction of cell migration (see Figure 17-47).

Perspectives for the Future

In this chapter, we have seen that cells have intricate mechanisms for the regulated spatial and temporal assembly and turnover of microfilaments to perform their many functions. Biochemical analyses of actin-binding proteins coupled with protein inventories provided by sequences of whole genomes have allowed the cataloging of many different classes of actin-binding proteins. To understand how this large group of proteins can assemble specific structures in a cell, it will be important to know the concentration of all the components, how they interact, and their regulation by signaling pathways. Although this might seem like a daunting task, new microscopic methods to detect the location of specific protein-protein interactions and the location of many of the key signaling pathways suggest that rapid progress will be made in this area.

The protein inventories provided by genomic sequences have also documented the large number of myosin families, yet the biochemical properties of many of these motors, or their biological functions, remain to be elucidated. Again, recent

technical developments, including the ability to tag motors with fluorescent tracers such as GFP, or knocking down their expression with RNAi technologies are providing very powerful avenues to help reveal motor functions. However, some important aspects of motors remain largely unexplored. For example, a motor that transports an organelle down a filament first has to bind the organelle, then transport it, and then release it at the destination. However, little is known about how these different events are coordinated or how these types of myosin-based motors are returned to pick up new cargo.

Twenty years ago it was believed that all actin assembly was driven by activation of the Arp2/3 complex. Then the nucleating and capping activities of formins were discovered, and more recently, additional actin nucleators, with colorful names such as Spire, Cordon-bleu, WASH, and WHAMM have been discovered. It is likely that additional nucleators will continue to be discovered.

Finally, although we have generally discussed microfilaments without regard to tissue type—except for the specializations found in skeletal and smooth muscles—many actin-binding proteins show cell-type-specific expression, and so the array and relative levels of these proteins are tailored to specific functions of different cell types. This is clearly the case, as revealed by proteomic analysis of cell-specific protein expression and by the fact that many diseases are a consequence of tissue-specific expression of actin-binding proteins or myosins.

Key Terms

actin 775	microtubules 775
actin cross-linking proteins 790	microvilli 773
Arp2/3 complex 784	motor protein 775
CapZ protein 783	myosin 793
Cdc42 protein 811	myosin light-chain kinase 805
cell migration 808	nucleation promoting factor (NPF) 785
cell polarity 774	power stroke 797
chemotaxis 813	profilin 782
cofilin 782	Rac protein 811
contractile bundles 804	Rho protein 811
critical concentration, C_c 779	skeletal muscle 793
cytoskeleton 774	smooth muscle 804
duty ratio 799	step size 799
F-actin 777	stress fibers 776
filopodia 776	thick filaments 801
formin 784	thin filaments 801
G-actin 777	thymosin β_4 783
intermediate filaments 775	treadmilling 781
lamellipodium 776	tropomodulin 783
leading edge 776	tropomyosin 803
microfilaments 775	WASp protein 785

Review the Concepts

1. Three systems of cytoskeletal filaments exist in most eukaryotic cells. Compare them in terms of composition, function, and structure.
2. Actin filaments have a defined polarity. What is filament polarity? How is it generated at the subunit level? How is filament polarity detectable?
3. In cells, actin filaments form bundles and/or networks. How do cells form such structures, and what specifically determines whether actin filaments will form a bundle or a network?
4. Much of our understanding of actin assembly in the cell is derived from experiments using purified actin *in vitro*. What techniques can be used to study actin assembly *in vitro*? Explain how each of these techniques works. Which of these techniques would tell you whether the mass of actin filaments is comprised of many short actin filaments or fewer longer filaments?
5. The predominant forms of actin inside a cell are ATP-G-actin and ADP-F-actin. Explain how the interconversion of the nucleotide state is coupled to the assembly and disassembly of actin subunits. What would be the consequence for actin filament assembly/disassembly if a mutation prevented actin's ability to bind ATP? What would be the consequence if a mutation prevented actin's ability to hydrolyze ATP?
6. Actin filaments at the leading edge of a crawling cell are believed to undergo treadmilling. What is treadmilling, and what accounts for this assembly behavior?
7. Although purified actin can assemble reversibly *in vitro*, various actin-binding proteins regulate the assembly of actin filaments in the cell. Predict the effect on a cell's actin cytoskeleton if function-blocking antibodies against each of the following are independently microinjected into cells: profilin, thymosin- β_4 , CapZ, and the Arp2/3 complex.
8. Predict how actin would polymerize on an arrowhead decorated seed (as shown in Figure 17-9) in the presence of CapZ, tropomodulin, or profilin-actin.
9. Compare and contrast the ways in which formin and WASp are activated, and how each stimulates actin filament formation.
10. There are at least 20 different types of myosin. What properties do all types share, and what makes them different? Why is myosin II the only myosin capable of producing contractile force?
11. The ability of myosin to walk along an actin filament may be observed with the aid of an appropriately equipped microscope. Describe how such assays are typically performed. Why is ATP required in these assays? How can such assays be used to determine the direction of myosin movement or the force produced by myosin?
12. Contractile bundles occur in nonmuscle cells; these structures are less organized than the sarcomeres of muscle cells. What is the purpose of nonmuscle contractile bundles? Which type of myosin is found in contractile bundles?
13. How does myosin convert the chemical energy released by ATP hydrolysis into mechanical work?

14. Myosin II has a duty ratio of 10 percent, and its step size is 8 nm. In contrast, myosin V has a much higher duty ratio (about 70 percent) and takes 36-nm steps as it walks down an actin filament. What differences between myosin II and myosin V account for their different properties? How do the different structures and properties of myosin II and myosin V reflect their different functions in cells?

15. Contraction of both skeletal and smooth muscle is triggered by an increase in cytosolic Ca^{2+} . Compare the mechanisms by which each type of muscle converts a rise in Ca^{2+} into contraction.

16. Phosphorylation of myosin light-chain kinase (MLCK) by protein kinase A (PKA) inhibits MLCK activation by Ca^{2+} -calmodulin. Drugs such as albuterol bind to β -adrenergic receptor, which causes a rise in cAMP in cells and activation of PKA activity. Explain why albuterol is useful for treating the severe contraction of the smooth muscle cells surrounding airway passages involved in an asthma attack.

17. Several types of cells utilize the actin cytoskeleton to power locomotion across surfaces. How are different assemblies of actin filaments involved in locomotion?

18. To move in a specific direction, migrating cells must utilize extracellular cues to establish which portion of the cell will act as the front and which will act as the back. Describe how G proteins appear to be involved in the signaling pathways used by migrating cells to determine direction of movement.

19. Cell motility has been described as being like the motion of tank treads. At the leading edge, actin filaments form rapidly into bundles and networks that make protrusions and move the cell forward. At the rear, cell attachments are broken and the tail end of the cell is brought forward. What provides the traction for moving cells? How does cell-body translocation happen? How are cell attachments released as cells move forward?

Analyze the Data

Myosin V is an abundant nonmuscle myosin that is responsible for the transport of cargo such as organelles in many cell types. Structurally, it consists of two identical polypeptide chains that dimerize to form a homodimer. The motor domains reside at the N-terminus of each chain and contain both ATP- and actin-binding sites. The motor domain is followed by a neck region containing six "IQ" motifs, each of which binds calmodulin, a Ca^{2+} -binding protein. The neck domain is followed by a region capable of forming coiled coils, via which the two chains dimerize. The final 400 amino acid residues form a globular tail domain (GTD), to which cargo binds. Myosin V would consume large amounts of ATP if its motor domain were always active, and a number of studies have been conducted to understand how this motor is regulated.

a. The rate of ATP hydrolysis (i.e., ATP molecules hydrolyzed per second per myosin V) was measured in the presence of increasing amounts of free Ca^{2+} . The concentration of cytosolic free Ca^{2+} is normally less than 10^{-6} M but can be elevated in localized areas of the cell and is often elevated in

response to a signaling event. What do these data suggest about myosin V regulation?

b. In additional studies, the ATPase activity of myosin V was measured in the presence of increasing amounts of F actin in the presence or absence of 10^{-6} M free Ca^{2+} . What additional information about myosin V regulation do these data provide?

c. Next, the behavior of truncated myosin V, which lacks just its C-terminal globular tail, was examined and compared to the behavior of intact myosin V. From this experiment, what can you deduce about the mechanism by which myosin V is regulated?

Looking at Muscle Contraction

H. Huxley and J. Hanson, 1954, *Nature* **173**:973–976

The contraction and relaxation of striated muscles allow us to perform all of our daily tasks. How does this happen? Scientists have long looked to see how fused muscle cells, called myofibrils, differ from other cells that cannot perform powerful movement. In 1954, Jean Hanson and Hugh Huxley published their microscopy studies on muscle contraction, which demonstrated the mechanism by which it occurs.

Background

The ability of muscles to perform work has long been a fascinating process. Voluntary muscle contraction is performed by striated muscles, which are named for their appearance when viewed under the microscope. By the 1950s, biologists studying myofibrils had named many of the structures they observed under the microscope. One contracting unit, called a sarcomere, is made up of two main regions called the A band and the I band. The A band contains two darkly colored thick striations and one thin striation. The I band is made up primarily of light-colored striations, which are divided by a darkly colored line known as the Z disk. Although these structures had been characterized, their role in muscle contraction remained unclear. At the same time, biochemists also tried to tackle this problem by looking for proteins that are more abundant in myofibrils than in nonmuscle cells. They found muscles to contain large amounts of the structural proteins actin and myosin in a complex with each other. Actin and myosin form polymers that can shorten when treated with adenosine triphosphate (ATP).

With these observations in mind, Hanson and Huxley began their study of cross striations in muscle. In a few short years, they united the biochemical

data with the microscopy observations and developed a model for muscle contraction that still holds true today.

The Experiment

Hanson and Huxley primarily used phase-contrast microscopy in their studies of striated muscles that they isolated from rabbits. The technique allowed them to obtain clear pictures of the sarcomere and to take careful measurements of the A and the I bands. By treating the muscles with a variety of chemicals, then studying them under the phase-contrast microscope, they were able to successfully combine biochemistry with microscopy to describe muscle structure as well as the mechanism of contraction.

In their first set of studies, Hanson and Huxley employed chemicals that are known to specifically extract either myosin or actin from myofibrils. First, they treated myofibrils with a chemical that specifically removes myosin from muscle. They used phase-contrast microscopy to compare untreated myofibrils to myosin-extracted myofibrils. In the untreated muscle, they observed the previously identified sarcomeric structure, including the darkly colored A band. When they looked at the myosin-extracted cells, however, the darkly colored A band was not observed. Next, they extracted actin from the myosin-extracted muscle cells. When they extracted both myosin and actin from the myofibril, they could see no identifiable structure to the cell under phase-contrast microscopy. From these experiments, they concluded that myosin was located primarily in the A band, whereas actin is found throughout the myofibril.

With a better understanding of the biochemical nature of muscle structures, Huxley and Hanson went on to study the mechanism of muscle contraction. They isolated individual myo-

fibrils from muscle tissue and treated them with ATP, causing them to contract at a slow rate. Using this technique, they could take pictures of various stages of muscle contraction observed using phase-contrast microscopy. They could also mechanically induce stretching by manipulating the coverslip, which allowed them to also observe the relaxation process. With these techniques in hand, they examined how the structure of the myofibril changes during contraction and stretch.

First, Huxley and Hanson treated myofibrils with ATP, then photographed the images they observed under phase-contrast microscopy. These pictures allowed them to measure the lengths of both the A band and the I band at various stages of contraction. When they looked at myofibrils freely contracting, they noticed a consistent shortening of the lightly colored I band, whereas the length of the A band remained constant (Figure 1). Within the A band, they observed the formation of an increasingly dense area throughout the contraction.

Next, the two scientists examined how the myofibril structure changes during a simulated muscle stretch. They stretched isolated myofibrils mounted on glass slides by manipulating the coverslip. They again photographed phase-contrast microscopy images and measured the lengths of the A and the I bands. During stretch the length of the I band increased, rather than shortened, as it had in contraction. Once again, the length of the A band remained unchanged. The dense zone that formed in the A band during contraction became less dense during stretch.

From their observations, Hanson and Huxley developed a model for muscle contraction and stretch (Figure 1). In their model, the actin filaments in the I band are drawn up into the A band during contraction, and thus

FIGURE 1 Schematic diagram of muscle contraction and stretch observed by Hanson and Huxley. The lengths of the sarcomere (S), the A band (A), and the I band (I) were measured in muscle samples contracted 60 percent in length relative to the relaxed muscle (*bottom*) or stretched to 120 percent (*top*). The lengths of the sarcomere, the I band, and the A band are noted on the right. Notice that from 120 percent stretch to 60 percent contraction the A band does not change in length. However, the length of the I band can stretch to 1.3 μm , and at 60 percent contraction, it disappears as the sarcomere shortens to the overall length of the A band. [Adapted from J. Hanson and H. E. Huxley, 1955, *Symp. Soc. Exp. Biol. Fibrous Proteins and Their Biological Significance* 9:249.]

the I band becomes shorter. This allows for increased interaction between the myosin located in the A band and the actin filaments. As the muscle stretches, the actin filaments withdraw from the A band. From these data, Hanson and Huxley proposed that muscle contraction is driven by actin filaments moving in and out of a mass of stationary myosin filaments.

Discussion

By combining microscopic observations with known biochemical treatments of muscle fibers, Hanson and Huxley were able to describe the biochemical nature of muscle structures and outline a mechanism for muscle contraction. A large body of research continues to focus on understanding

the process of muscle contraction. Scientists now know that muscles contract by ATP hydrolysis, driving a conformational change in myosin that allows it to pull on actin. Researchers are continuing to uncover the molecular details of this process, whereas the mechanism of contraction proposed by Hanson and Huxley remains in place.

Cell Organization and Movement II: Microtubules and Intermediate Filaments

As we learned in the previous chapter, three types of filaments make up the animal-cell cytoskeleton: microfilaments, microtubules, and intermediate filaments. Why have these three distinct types of filaments evolved? It seems likely that their physical properties are suited to different functions. In Chapter 17 we described how actin microfilaments are often cross-linked into networks of bundles to form flexible and dynamic structures and to serve as tracks for the many different classes of myosin motors. Likewise, **microtubules** are stiff tubes that can exist as a single structure extending up to 20 μm in cells, or in bundled arrangements such as those seen in specialized cell surface structures like cilia and flagella. A consequence of their tubular design is the ability of microtubules to generate pulling and pushing forces without buckling, a property that allows single tubules to extend large distances within a cell and bundles to slide past each other, as occurs in flagella and in the mitotic spindle. Microtubules' ability to extend long distances in the cell, together with their intrinsic polarity,

is exploited by microtubule-dependent motors, which use microtubules as tracks for long-range transport of organelles. Microtubules can be highly dynamic—being assembled and disassembled from their ends—providing the cell with the flexibility to alter microtubule organization as needed.

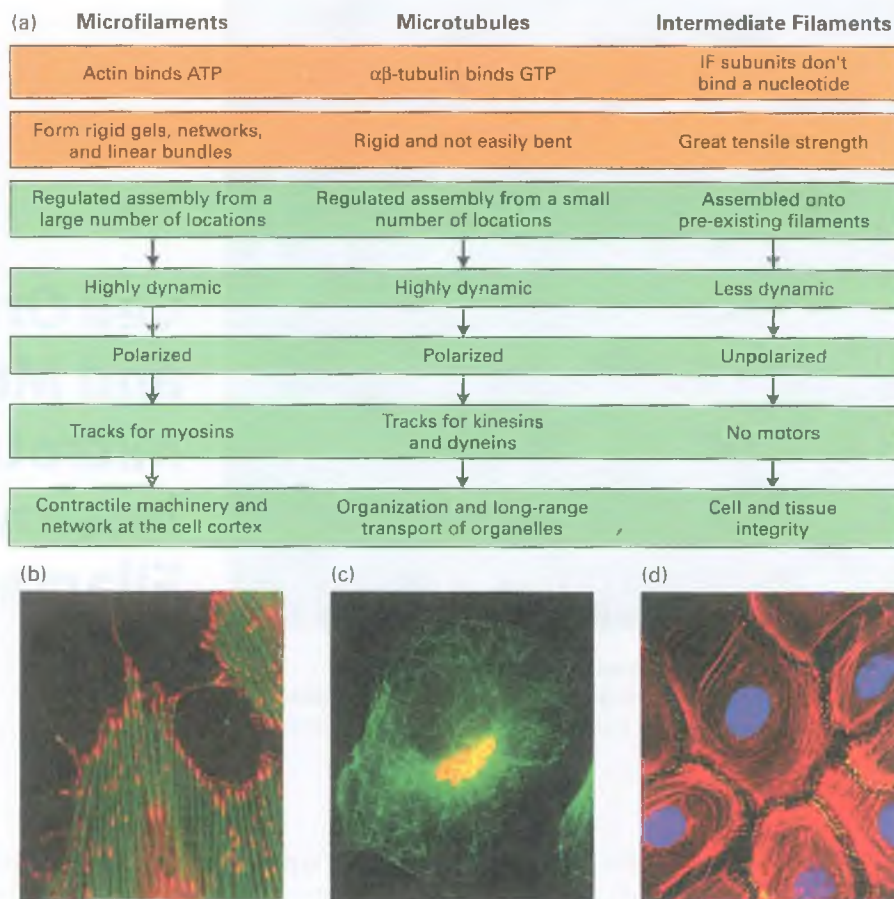

In contrast to microfilaments and microtubules, **intermediate filaments** have great tensile strength and have evolved to withstand much larger stresses and strains. With properties akin to strong molecular ropes, they are ideally suited to endow both cells and tissues with structural integrity and contribute to cellular organization. Intermediate filaments do not have an intrinsic polarity like microfilaments and microtubules, so it is not surprising that there are no known motor proteins that use intermediate filaments as tracks. Although we discuss microtubules and intermediate filaments together in this chapter—and their localization in the cytoplasm can look superficially quite similar—we will see their dynamics and functions are very different. A summary of the similarities and differences among the three cytoskeletal systems is presented in Figure 18-1.

Cytokeratins from individual cells are attached to each other through the desmosomes. [Part (b) courtesy of K. Burridge. Part (c) courtesy of W. Brown. Part (d) courtesy of E. Fuchs.]

This chapter covers five main topics. First, we discuss the structure and dynamics of microtubules and their motor proteins. Second, we examine how microtubules and their motors contribute to the movement of cilia and flagella. Third, we discuss the role of microtubules in the mitotic spindle—a molecular machine that accurately segregates duplicated chromosomes. Fourth, we explore the roles of the different classes of intermediate filaments that provide structure to the nuclear envelope as well as strength and organization to cells and tissues. Although we consider microtubules, microfilaments, and intermediate filaments individually, the three cytoskeletal systems do not act independently of one another, and we consider some examples of this interdependence in the last section of the chapter.

18.1 Microtubule Structure and Organization

In the early days of electron microscopy, cell biologists noted long tubules in the cytoplasm that they called **microtubules**. Morphologically similar microtubules were seen making up the fibers of the mitotic spindle, as components of axons, and as the structural elements in cilia and flagella (Figure 18-2a, b).

A careful examination of single microtubules from various sources seen in transverse section indicated that they are all made up of 13 longitudinal repeating units (Figure 18-2c), now called *protofilaments*, suggesting the various microtubules all have a common structure. Microtubules purified from brain were then found to consist of a major protein, **tubulin**, and associated proteins, **microtubule-associated proteins (MAPs)**. Purified tubulin alone can assemble into a microtubule under favorable conditions, proving that it is the structural component of the microtubule wall. MAPs, as we shall see, help mediate the assembly and dynamics of microtubules. In this section we consider the general structure and organization of microtubules, before turning to a more detailed discussion of their dynamics and regulation in Sections 18.2 and 18.3.

Microtubule Walls Are Polarized Structures Built from $\alpha\beta$ -Tubulin Dimers

Tubulin isolated in a pure and soluble form consists of two closely related subunits called α - and β -tubulin, each with a molecular weight of about 55,000 daltons. Genomic analyses reveal that genes encoding both α - and β -tubulins are present in all eukaryotes, with considerable expansion of the number of genes in multicellular organisms. For example, budding

FIGURE 18-2 Microtubules are found in many different locations, and all have similar structures. (a) Surface of the ciliated epithelium lining a rabbit oviduct viewed in a scanning electron microscope. Beating cilia, which have a core of microtubules, propel eggs down the oviduct. (b) Microtubules and intermediate filaments in a quick-frozen and deep-etched frog axon visualized in a transmission electron

microscope. (c) High-magnification view of a single microtubule showing 13 repeating units known as protofilaments. [Part (a) from R. G. Kessels and R. H. Kardon, 1975, *Tissues and Organs*, W. H. Freeman and Company. Part (b) from N. Hirokawa, 1982, *J. Cell Biol.* **94**:129; courtesy of N. Hirokawa. Part (c) courtesy C. Bouchet-Marquis, 2007, *Biology of the Cell* **99**:45.]

yeast has two genes specifying α -tubulin and one for β -tubulin, whereas the soil nematode *Caenorhabditis elegans* has nine genes encoding α -tubulin and six for β -tubulin. In addition to α - and β -tubulin, all eukaryotes also have genes specifying a third tubulin, γ -tubulin, which is involved in microtubule assembly, as we discuss shortly. Additional isoforms of tubulin have also been discovered that are present only in organisms that possess cellular structures called centrioles and basal bodies, suggesting that these tubulin isoforms are important for those structures. As we'll learn in this chapter, centrioles and basal bodies are specialized structures that some organisms use to nucleate and organize microtubule assembly.

The α - and β -subunits of the tubulin dimer can each bind one molecule of GTP (Figure 18-3a). The GTP in the α -tubulin subunit is never hydrolyzed and is trapped by the interface between the α - and β -subunits. By contrast, the GTP-binding site on the β -subunit is at the surface of the dimer. GTP bound by the β -subunit can be hydrolyzed, and the resulting

GDP can be exchanged for free GTP. Under appropriate conditions, soluble tubulin dimers can assemble into microtubules (Figure 18-3b). As we saw in Chapter 17 for the polymerization of actin, ATP-G actin is preferentially added to one end of the filament, designated the (+) end because it is the end favored for assembly. Once incorporated into the filament, the bound ATP is hydrolyzed to ADP and P_i . In a similar manner, tubulin dimers in which the β -subunit has bound GTP add preferentially to one end of the microtubule, also designated the (+) end. As we will see, the GTP is hydrolyzed once tubulin is incorporated into the microtubule, but in contrast to the situation with ATP hydrolysis in an actin filament, this GTP hydrolysis has dramatic effects on the behavior of the microtubule (+) end.

Microtubules are composed of 13 laterally associated protofilaments that form a tubule whose external diameter is about 25 nm (see Figure 18-3b). Each of the 13 protofilaments is a string of $\alpha\beta$ -tubulin dimers, longitudinally arranged

FIGURE 18-3 Structure of tubulin dimers and their organization into microtubules. (a) Ribbon diagram of the tubulin dimer. The GTP bound to the α -tubulin monomer is nonexchangeable, whereas the GDP bound to the β -tubulin monomer is exchangeable with free GTP. (b) The organization of tubulin subunits in a microtubule. The dimers are aligned end to end into protofilaments, which pack side by side to form the wall of the microtubule. The protofilaments are slightly staggered so that α -tubulin in one protofilament is in contact with α -tubulin in the neighboring protofilaments, except at the seam, where an α -subunit contacts a β -subunit. The microtubule displays a structural polarity in that subunits are added preferentially at the end where β -tubulin monomers are exposed. This end of the microtubule is known as the (+) end. [Part (a) modified from E. Nogales et al., 1998, *Nature* 391:199; courtesy of E. Nogales.]

so that the subunits alternate down a protofilament, with each subunit type repeating every 8 nm. Because the $\alpha\beta$ -tubulin dimers in a protofilament are all oriented in the same way, each protofilament has an α -subunit at one end and a β -subunit at the other—so the protofilaments have an intrinsic

polarity. In a microtubule, all the laterally associated protofilaments have the same polarity, thus the microtubule also has an overall polarity. The end with exposed β -subunits is the (+) end, while the end with exposed α -subunits is the (–) end. In microtubules, the heterodimers in adjacent protofilaments are staggered slightly, forming tilted rows of α - and β -tubulin monomers in the microtubule wall. If you follow a row of β -subunits, for example, spiraling around a microtubule for one full turn, you will end up precisely three subunits up the protofilament, abutting an α -subunit. Thus all microtubules have a single longitudinal *seam*, where an α -subunit in one protofilament meets a β -subunit in the adjacent protofilament.

Most microtubules in a cell consist of a simple tube, a *singlet* microtubule, built from 13 protofilaments. In rare cases, singlet microtubules contain more or fewer protofilaments; for example, certain microtubules in the neurons of nematode worms contain 11 or 15 protofilaments. In addition to the simple singlet structure, *doublet* or *triplet* microtubules are found in specialized structures such as cilia and flagella (doublet microtubules) and centrioles and basal bodies (triplet microtubules), structures we will explore later in the chapter. Each doublet or triplet contains one complete 13-protofilament microtubule (called the A tubule) and one or two additional tubules (B and C) consisting of 10 protofilaments each (Figure 18-4).

Microtubules Are Assembled from MTOCs to Generate Diverse Organizations

With the identification of tubulin as the major structural component of microtubules, antibodies to tubulin were generated and used in immunofluorescence microscopy to localize microtubules in cells (Figure 18-5a, b). This approach, coupled with the description of microtubules seen by electron microscopy, showed that microtubules are assembled from specific sites to generate many different types of organization.

The nucleation phase of microtubule assembly is such an unfavorable reaction that spontaneous nucleation does not play a significant role in microtubule assembly in vivo. Rather, all microtubules are nucleated from structures known as **microtubule-organizing centers**, or **MTOCs**. In most cases the (–) end of the microtubule stays anchored in the MTOC while the (+) end extends away from it.

The **centrosome** is the main MTOC in animal cells. In non-mitotic cells, also known as *interphase* cells, the centrosome

FIGURE 18-4 Singlet, doublet, and triplet microtubules. In cross section, a typical microtubule, a singlet, is a simple tube built from 13 protofilaments. In a doublet microtubule, an additional set of 10 protofilaments forms a second tubule (B) by fusing to the wall of a singlet (A) microtubule. Attachment of another 10 protofilaments to the (B) tubule of a doublet microtubule creates a (C) tubule and a triplet structure.

FIGURE 18-5 Microtubules are assembled from microtubule organizing centers (MTOCs). The distribution of microtubules in cultured cells as seen by immunofluorescence microscopy using antibodies to tubulin in an interphase cell (a) and a cell in mitosis (b). (c–f) Diagrams of the distribution of microtubules in cells and structures, all of which are assembled from distinct MTOCs. In an interphase cell (c), the MTOC is called a centrosome (the nucleus is indicated by a blue oval); in a mitotic cell (d), the two MTOCs are called

spindle poles (the chromosomes are shown in blue); in a neuron (e), microtubules in both axons and dendrites are assembled from an MTOC in the cell body and then released from it; the microtubules that make up the shaft of a cilium or flagellum (f) are assembled from an MTOC known as a basal body. The polarity of microtubules is indicated by (+) and (–). [Part (a) courtesy of A. Bretscher. Part (b) courtesy of T. Wittmann.]

is generally located near the nucleus, producing an array of microtubules with their (+) ends radiating toward the cell periphery (Figure 18-5c). This radial display provides tracks for microtubule-based motor proteins to organize and transport membrane-bound compartments, such as those comprising the secretory and endocytic pathways. During mitosis, cells completely reorganize their microtubules to form a bipolar spindle, assembled from two centrosomes, also known as *spindle poles*, to accurately segregate copies of the duplicated chromosomes (Figure 18-5d). In another example, neurons have long processes called axons, in which organelles are transported in both directions along microtubules (Figure 18-5e). The microtubules in axons, which can be as long as 1 meter in length, are not continuous and have been released from the centrosome but nevertheless are all of the same polarity. In the same cells, the microtubules in the dendrites have mixed polarity, although the functional significance of this is not clear. In cilia and flagella (Figure 18-5f), microtubules are assembled from an MTOC called a *basal body*. As we mention later, plants do not have centrosomes and basal bodies but use other mechanisms to nucleate the assembly of microtubules.

Electron microscopy shows that centrosomes in animal cells consist of a pair of orthogonally arranged cylindrical centrioles surrounded by apparently amorphous material called *pericentriolar material* (Figure 18-6a, arrowheads). Centrioles, which are about 0.5 μm long and 0.2 μm in diameter,

are highly organized and stable structures that consist of nine sets of triplet microtubules and are closely related in structure to the basal bodies found at the base of cilia and flagella. It is not the centrioles themselves that nucleate the cytoplasmic microtubule array, but rather factors in the pericentriolar material. A critical component is the *γ -tubulin ring complex* (*γ -TuRC*) (Figures 18-6b and 18-7). *γ -TuRC* is located in the pericentriolar material and consists of many copies of γ -tubulin associated with several other proteins. It is believed that *γ -TuRC* acts like a split-washer template to bind $\alpha\beta$ -tubulin dimers for the formation of a new microtubule, with the (–) end associated with *γ -TuRC* and the (+) end free for assembly. In addition to nucleating the assembly of microtubules, centrosomes anchor and regulate the dynamics of the (–) ends of the microtubules, which are located there.

Basal bodies have a structure similar to the centriole and are the MTOCs found at the base of cilia and flagella. The A and B tubules of their triplet microtubules provide a template for the assembly of the microtubules making up the core structure of cilia and flagella.

Recent work has uncovered an additional mechanism for the nucleation of microtubules in animal cells, also involving *γ -TuRC*. A protein complex called the *augmin complex*, consisting of eight polypeptides, can bind to the side of existing microtubules, then recruit *γ -TuRC* and nucleate the assembly of new ones. As we discuss in a later section, the augmin complex contributes to microtubule assembly in the mitotic spindle.

FIGURE 18-6 Structure of centrosomes. (a) Thin section of an animal-cell centrosome showing the two centrioles at right angles to each other surrounded by pericentriolar material (arrows). (b) Diagram of a centrosome showing the mother and daughter centrioles, each of which consists of nine linked outer triplet microtubules embedded in pericentriolar material that contains γ -TuRC nucleating structures.

The mother centriole is distinct from the daughter as it has distal appendages (blue spheres). KEY CONCEPTS of Section 18.1

Microtubule Structure and Organization

- Tubulin is the major structural component of microtubules (see Figure 18-3) with which microtubule-associated proteins (MAPs) associate.
- Free tubulin exists as an $\alpha\beta$ -dimer, with the α -subunit binding a trapped and nonhydrolyzable GTP and the β -subunit binding an exchangeable and hydrolyzable GTP.
- $\alpha\beta$ -tubulin assembles into microtubules having 13 laterally associated protofilaments, with an α -subunit exposed at the (–) end and a β -subunit at the (+) end of each protofilament.
- In cilia and flagella, as well as in centrioles and basal bodies, doublet or triplet microtubules exist in which the additional microtubules have 10 protofilaments (see Figure 18-4).
- All microtubules are nucleated from microtubule-organizing centers (MTOCs), and many remain anchored with their (–) end there. Thus the end away from the MTOC is always the (+) end.
- The centrosome is the MTOC that nucleates the radial array of microtubules in non-mitotic animal cells; two centrosomes, or spindle poles, are the MTOCs that nucleate the microtubules of the mitotic spindle; and basal bodies are the MTOCs that assemble microtubules of cilia and flagella (see Figure 18-5).
- Centrosomes consist of two centrioles and the pericentriolar material that contains the γ -TuRC microtubule-nucleating complex (see Figures 18-6 and 18-7).

FIGURE 18-7 The γ -tubulin ring complex (γ -TuRC) that nucleates microtubule assembly. (a) An immunofluorescence micrograph of in vitro assembled microtubules is labeled green and a component of the γ -TuRC is labeled red, showing that it is located specifically at one end of the microtubule. (b) Model of how γ -TuRC may nucleate assembly of a microtubule by forming a template corresponding to the (–) end of a microtubule. [Part (a) Modified from T. J. Keating and G. G. Borisy, 2000, *Nature Cell Biol.* 2:352; courtesy of T. J. Keating and G. G. Borisy.]

18.2 Microtubule Dynamics

Microtubules are dynamic structures due to assembly and disassembly at their ends. The degree of dynamics can vary enormously, with an average microtubule lifetime of less than 1 minute for cells in mitosis and about 5–10 minutes for the microtubules that make up the radial array seen in nonmitotic animal cells. Microtubule lifetime is longer in axons and much longer in cilia and flagella. To elucidate how these differences occur, we discuss the dynamic properties of microtubules and how this behavior contributes to their cellular organization.

Individual Microtubules Exhibit Dynamic Instability

Early experiments revealed that most microtubules in animal cells will disassemble when the cells are cooled to 4 °C, and will repolymerize when the cells are warmed back to 37 °C. Researchers realized that this intrinsic property of microtubules could be exploited to purify the components of microtubules. Since brain tissue is rich in microtubules, soluble extracts of pig brains were prepared at 4 °C; these clarified extracts were then warmed to 37 °C to induce microtubule assembly. The assembled microtubules were collected into a pellet by centrifugation, separated from the supernatant, and then disassembled by adding buffer at 4 °C. After another cycle of assembly by warming, collection, and disassembly by cooling, researchers recovered *microtubular protein*, a collective term for $\alpha\beta$ -tubulin and microtubule-associated proteins (MAPs). They were then able to fractionate the microtubular protein into pure $\alpha\beta$ -tubulin and MAPs, to study their behaviors separately. Investigators found that polymerization of dimeric $\alpha\beta$ -tubulin into microtubules is greatly catalyzed by the presence of the MAPs.

Although a tremendous amount of research effort was devoted to characterizing the bulk polymerization properties of microtubular protein in solution, its general relevance was superseded by subsequent studies examining the properties of individual microtubules. Nevertheless, some lessons learned from the earlier in vitro studies are important to microtubule biology. First, for assembly to occur, the $\alpha\beta$ -tubulin concentration must be above the *critical concentration* (C_c), just as we saw for actin polymerization (see Figure 17-8). Second, at $\alpha\beta$ -tubulin concentrations higher than the C_c for polymerization, dimers add faster to one end of the microtubule than to the other (Figure 18-8). As with F-actin assembly, the preferred end for assembly is designated the (+) end, which is the end with β -tubulin exposed. The (–) end has α -tubulin exposed (see Figure 18-3b).

When studying the bulk properties of microtubule assembly, one assumes that all microtubules are behaving similarly. However, when researchers examined the behavior of individual microtubules within a population, they found this was not the case. Individual microtubule behavior was examined in a very simple experiment. Microtubules were assembled

EXPERIMENTAL FIGURE 18-8 Microtubules grow preferentially at the (+) end. A fragment of a microtubule bundle from a flagellum was used as a nucleus for the in vitro addition of $\alpha\beta$ -tubulin. The nucleating flagellar fragment is the thick bundle seen in this electron micrograph, with the newly formed microtubules (MT) radiating from its ends. The greater length of the microtubules at one end, the (+) end, indicates that tubulin subunits are added preferentially to this end. [Courtesy of G. Borisy.]

in vitro and then sheared to break them into shorter pieces whose individual lengths could be analyzed by microscopy. Under these conditions, one would expect all the short microtubules to either grow or shrink, depending on the free tubulin concentration. However, the investigators found that some of the microtubules grew in length, whereas others shortened very rapidly—thus indicating the existence of two distinct populations of microtubules. Further studies showed that individual microtubules could grow and then suddenly experience a *catastrophe* to a shrinking phase during which the microtubule undergoes rapid depolymerization. Moreover, sometimes a depolymerizing microtubule end could go through a *rescue* and begin growing again (Figure 18-9). Although this phenomenon was first seen in vitro, analysis of fluorescently labeled tubulin microinjected into live cells showed that microtubules in cells also undergo periods of

FIGURE 18-9 Dynamic instability of microtubules in vitro.

Individual microtubules can be observed in the light microscope and their lengths plotted at different times during assembly and disassembly. Assembly and disassembly each proceed at uniform rates, but there is a big difference between the rate of assembly and that of disassembly, as seen in the different slopes of the lines. Shortening of a microtubule is much more rapid ($7 \mu\text{m}/\text{min}$) than growth ($1 \mu\text{m}/\text{min}$). Notice the abrupt transitions to the shrinkage stage (catastrophe) and to the elongation stage (rescue). [Adapted from P. M. Bayley, K. K. Sharma, and S. R. Martin, 1994, in *Microtubules*, Wiley-Liss, p. 118.]

growth and shrinkage (Figure 18-10). This process of alternating between growing and shrinking states is known as *dynamic instability*. Thus the dynamic life of a microtubule end is determined by the rate of growth, the frequency of catastrophes, the rate of depolymerization, and the frequency of rescues. As we see later, these features of microtubule dynamics are controlled *in vivo*. Since the $(-)$ ends of microtubules in animal cells are generally anchored on an MTOC, this dynamic nature is most relevant to the $(+)$ end of the microtubule.

What is the molecular basis of dynamic instability? If you look carefully by electron microscopy at the ends of growing and shrinking microtubules, you can see they are

quite different. A growing microtubule has a relatively blunt end, whereas a depolymerizing end has protofilaments peeling off like rams' horns (Figure 18-11). In fact, the growing microtubule end is not simply a blunt end but rather a short and flat sheet-like structure, made by the addition of tubulin dimers to the ends of protofilaments, that then rolls up along the seam to make the cylindrical microtubule.

Recent studies have provided a simple structural explanation for the two classes of microtubule ends. As we noted above, the β -subunit of the $\alpha\beta$ -tubulin dimer is exposed on the $(+)$ end of each protofilament. Using a GDP analog, researchers have found that artificially made *single* protofilaments—where there are no lateral interactions—made up of repeating $\alpha\beta$ -tubulin dimers containing GDP- β -tubulin are curved, like a ram's horn. However, artificially made single protofilaments made up of $\alpha\beta$ -tubulin dimers containing GTP- β -tubulin are straight. Thus growing microtubules with blunter ends terminate in GTP- β -tubulin, whereas shrinking ones with curled ends terminate in GDP- β -tubulin. Therefore, if the GTP molecules in the terminal β -tubulins become hydrolyzed on a microtubule that has stopped growing, a formerly blunt-end microtubule will curl and a catastrophe ensues. These relationships are summarized in Figure 18-11.

These results have an additional implication, and to understand this we have to consider the growing microtubule in more detail. The addition of a dimer to the $(+)$ end of a protofilament on a growing microtubule involves an interaction between the preexisting terminal β -subunit and the new α -subunit. This interaction enhances the hydrolysis of the GTP to GDP in the formerly terminal β -subunit. However, the β -tubulin in the newly added dimer contains GTP. Thus each protofilament in a growing microtubule has mostly GDP- β -tubulin down its length and is capped by one or two terminal dimers containing GTP- β -tubulin. As we mentioned above, an *isolated* protofilament containing GDP- β -tubulin is curved along its length, so when it is present in a microtubule, why doesn't it break out and peel away? The lateral protofilament-protofilament interactions in the β -tubulin-GTP cap are sufficiently strong that they do

VIDEO: Assembly of Microtubules in Cultured Cells

EXPERIMENTAL FIGURE 18-10 Fluorescence microscopy reveals growth and shrinkage of individual microtubules in vivo. Fluorescently labeled tubulin was microinjected into cultured human fibroblasts. The cells were chilled to depolymerize preexisting microtubules into tubulin dimers and were then incubated at 37°C to allow repolymerization, thus incorporating the fluorescent tubulin into all the cells' microtubules. A region of a cell periphery was viewed in the fluorescence microscope at 0 second, 27 seconds later, and 3 minutes 51 seconds later (left to right panels). In this period, several microtubules can be seen to have elongated and shortened. The dots labeled A, B, and C mark the position of the ends of three microtubules. [Modified from P. J. Sammak and G. Borisy, 1988, *Nature* **332**:724.]

FIGURE 18-11 Dynamic instability depends on the presence or absence of a GTP- β -tubulin cap. Images taken in the electron microscope of frozen samples of a growing microtubule (upper) and a shrinking microtubule (lower). Notice that the end of the growing microtubule has a blunter end, whereas the shrinking one has curls like a ram's horns. The diagram shows that a microtubule with GTP- β -tubulin on the end of each protofilament is strongly favored to grow. However, a microtubule with GDP- β -tubulin at the ends of the protofilaments forms a curved structure and will undergo rapid disassembly. Switching between growing and shrinking phases, called rescues and catastrophes, can occur, and the rate of switching is regulated by associated proteins. [Images from E-M Mandelkow et al., 1991, *J. Cell Biol.* **114**:977. Diagram modified from A. Desai and T. J. Mitchison, 1997, *Annu. Rev. Cell Dev. Biol.* **13**:83–117.]

not allow the microtubule to unpeel at its end—and so the protofilaments behind the GTP- β -tubulin cap are constrained from unpeeling (see Figure 18-11). The energy released by GTP hydrolysis of the subunits behind the cap is stored within the lattice as structural strain waiting to be released when the GTP- β -tubulin cap is lost. If the GTP- β -tubulin cap is lost, the stored energy can do work if some structure, such as a chromosome, is attached to the disassembling microtubule end. As we will see, this stored energy

contributes to the movement of chromosomes during the anaphase stage of mitosis.

How can a disassembling microtubule suddenly be rescued to grow again? A possible answer to this perplexing problem has recently been suggested. Using an antibody that only recognizes GTP- β -tubulin and not GDP- β -tubulin, researchers have found that “islands” of GTP- β -tubulin can occur along the length of an assembled microtubule. It seems likely that when a disassembling microtubule encounters one of these GTP- β -tubulin islands, disassembly pauses and may provoke a rescue.

Localized Assembly and “Search-and-Capture” Help Organize Microtubules

We have now presented two major concepts relating to microtubule organization and (+) end dynamics: microtubules are assembled from localized sites known as MTOCs, and individual microtubules can undergo dynamic instability. Together these two processes contribute to the distribution of microtubules in cells.

In an interphase cell growing in culture, microtubules are constantly being nucleated from the centrosome and spreading out, randomly “searching” the cytoplasmic space. The frequency of catastrophes and rescues, together with growth and shrinkage rates, determines the length of each microtubule—if the microtubule is subject to a high catastrophe frequency and low rescue, it will shrink back to the centrosome and disappear, whereas if it has few catastrophes and is readily rescued, it will continue to grow. If the searching microtubule encounters an appropriate target on a cell structure or organelle, the microtubule end may become attached to the structure. Organelle or cell structure “capture” by the microtubule stabilizes its (+) end and protects it from catastrophes, whereas unattached microtubules have a greater frequency of being disassembled. So the dynamics of the microtubule end is a very important determinant of microtubule life cycle and function. “Search and capture” is part of the mechanism determining the overall organization of microtubules in a cell. Moreover, by changing the rate of nucleation or local microtubule dynamics and capture sites, a cell can rapidly change its overall microtubule distribution. We will see later that this is what happens as cells enter mitosis.

Drugs Affecting Tubulin Polymerization Are Useful Experimentally and in Treatment of Diseases

 The conserved nature of tubulins and their essential involvement in critical processes such as mitosis make them prime targets for both naturally occurring and synthetic drugs that affect polymerization or depolymerization. Historically, the first known such drug was colchicine, present in extracts of the meadow saffron, which binds tubulin dimers so that they cannot polymerize into a microtubule. Since most microtubules are in a dynamic state between dimers and

EXPERIMENTAL FIGURE 18-12 Microtubules grow from the MTOC. To investigate from where microtubules assemble in vivo, a cultured fibroblast was treated with colchicine until almost all the cytoplasmic microtubules were disassembled. The cell was then stained with antibodies to tubulin and viewed by immunofluorescence microscopy (a). The colchicine was then washed out to allow the reassembly of microtubules. Panel (b) shows the first stages of reassembly, revealing microtubules growing from the MTOC in the central region above the nucleus (dark areas). Note in panel (a) the remaining primary cilium (arrowhead; discussed in Section 18.5) associated with the centrosome; it is not depolymerized by colchicine treatment under these conditions. Note also the fluorescence from the cytoplasm, which is from unpolymerized $\alpha\beta$ -tubulin dimers. [From M. Osborn and K. Weber, 1976, *Proc. Natl. Acad. Sci. USA* **73**:867–871.]

polymers, the addition of colchicine sequesters all free dimers in the cytoplasm, resulting in loss of microtubules due to their natural turnover. Treatment of cultured cells with colchicine for a short time results in the depolymerization of all the cytoplasmic microtubules, leaving the more stable tubulin-containing centrosome (Figure 18-12a). When the colchicine is washed out to allow regrowth of the microtubules, they can be seen to grow from the centrosome, revealing its ability to nucleate new microtubule assembly (Figure 18-12b).

Colchicine has been used for hundreds of years to relieve the joint pain of acute gout—a famous patient was King Henry VIII of England, who was treated with colchicine to relieve this ailment. A low level of colchicine relieves the inflammation caused in gout by reducing the microtubule dynamics of white blood cells, rendering them unable to migrate efficiently to the site of inflammation.

In addition to colchicine, a number of other drugs bind the tubulin dimer and restrain it from forming polymers. These include podophyllotoxin (from juniper) and nocodazole (a synthetic drug).

Taxol, a plant alkaloid from the Pacific yew tree, binds and stabilizes microtubules against depolymerization. Because taxol stops cells from dividing by inhibiting mitosis, it has been used to treat some cancers, such as those of the breast and ovary, where the cells are especially sensitive to the drug. ■

KEY CONCEPTS of Section 18.2

Microtubule Dynamics

- Individual microtubule (+) ends can undergo dynamic instability, with alternating periods of growth or rapid shrinkage (see Figure 18-10).
- Most of the β -tubulin in microtubules is bound to GDP. In growing microtubules, the (+) ends are capped by GTP- β -tubulin and are blunt or slightly splayed out. Shrinking microtubules have lost the GTP- β -tubulin cap, causing the protofilaments to peel outward and disassemble (see Figure 18-11).
- Growing microtubules store the energy derived from GTP hydrolysis in the microtubule lattice, so they have the potential to do work when disassembling.
- Microtubules assembled from the centrosome and exhibiting dynamic instability can “search” the cytoplasm for structures or organelles with appropriate targets and “capture” them, resulting in stabilization of the microtubule (+) end. In this way, assembly coupled with “search and capture” can contribute to the overall distribution of microtubules in a cell.

18.3 Regulation of Microtubule Structure and Dynamics

The wall of microtubules is built from $\alpha\beta$ -tubulin dimers, and highly purified $\alpha\beta$ -tubulin will assemble in vitro into microtubules. But assembly of microtubules in vitro can be greatly enhanced by the presence of stabilizing microtubule-associated proteins (MAPs). Stabilizing MAPs represent just one class of protein that interacts with tubulin in microtubules; other classes destabilize microtubules, or modify their growth properties. We discuss the various classes in this section. The regulation of microtubule structure and dynamics is critical for proper cell function. As we will see later, microtubules are the major organizers of organelles in animal cells, and their stability and dynamics are tailored for the specific function of the cell at any given time. For example, the dynamics of microtubules increase dramatically as cells enter mitosis to allow the cell to build a new microtubule organization, the mitotic spindle.

Microtubules Are Stabilized by Side-Binding Proteins

Several different classes of proteins stabilize microtubules, many of them showing cell-type-specific expression. Among the best studied are the *tau* family of proteins, which includes tau itself, and proteins called MAP2 and MAP4. Tau and MAP2 are neuronal proteins, while MAP4 is expressed by other cell types and is generally not present in neurons. These proteins have a modular design with two key domains.

EXPERIMENTAL FIGURE 18-13 Spacing of microtubules depends on the length of the projection domain of microtubule-associated proteins. Insect cells transfected to express MAP2, which has a long arm, or to express tau protein, which has a short arm, grow long axonlike processes. (a) Electron micrographs of cross sections through the processes induced by the expression of MAP2 (left) or tau (right) in transfected cells. Note that the spacing between microtubules (MTs) in MAP2-containing cells is larger than in tau-containing cells. Both cell types contain approximately the same number of microtubules, but the effect of MAP2 is to enlarge the caliber of the axonlike process. (b) Diagrams of association between microtubules and MAPs. Note the difference in the lengths of the projection arms in MAP2 and tau. [Part (a) from J. Chen et al., 1992, *Nature* 360:674.]

One domain consists of a positively charged 18-residue sequence, repeated three to four times, that binds to the negatively charged tubulin surface. The second domain projects out at a right angle from the microtubule (Figure 18-13). Tau proteins are believed to stabilize microtubules and also to act as spacers between them. MAP2 is found only in dendrites of neurons, where it forms fibrous cross-bridges between microtubules and links microtubules to intermediate filaments. Tau, which is much smaller than most other MAPs, is present in both axons and dendrites. The basis for this selectivity is still a mystery.

When stabilizing MAPs coat the outer wall of a microtubule, they can increase the growth rate of microtubules or suppress the catastrophe frequency. In many cases, the activity of the MAPs is regulated by the reversible phosphoryla-

tion of their projection domain. Phosphorylated MAPs are unable to bind to microtubules; thus phosphorylation promotes microtubule disassembly. For example, microtubule-affinity-regulating kinase (MARK/Par-1) is a key modulator of tau proteins. Some MAPs, like MAP4, are also phosphorylated by a *cyclin-dependent kinase* (CDK) that plays a major role in controlling the activities of proteins in the course of the cell cycle (Chapter 19).

+TIPs Regulate the Properties and Functions of the Microtubule (+) End

In addition to the side-binding MAPs like the tau proteins, MAPs have been identified that associate with the (+) ends of microtubules. In many cases, they only associate with (+) ends that are growing, not shrinking (Figure 18-14a, b). The MAPs in this class are known as +TIPs, for plus-end tracking proteins. Although there are various mechanisms by which +TIPs recognize a growing (+) microtubule end, the association of a major +TIP called EB1 (end binding-1) is believed to be through interaction with a unique structure only present in growing microtubules (Figure 18-14c). The most obvious unique feature of a growing microtubule is the more blunt nature of its (+) end, so perhaps this is what EB1 recognizes. However, the localization of EB1 extends much farther back along the microtubule than just the very tip with the blunt end, suggesting that this simple model is not telling the whole story. Most other +TIPs associate with the (+) end by either binding EB1, or requiring EB1 for their association there, and are generally said to be “hitchhiking” on EB1 (see Figure 18-14d).

+TIPs are very important in the life of a microtubule, as they can modify its properties in several ways. First, proteins such as EB1 promote microtubule growth by enhancing polymerization at the (+) end. Second, other +TIPs can reduce the frequency of catastrophes, thereby also promoting microtubule growth. A third class links the microtubule (+) end to other cellular structures, such as the cell cortex, F-actin, and as we will see later during our discussion of mitosis, chromosomes; a key feature of this dynamic system is that when “searching” microtubules grow and a +TIP encounters an appropriate target, the microtubule can become “captured” and stabilized. Yet other +TIPs link microtubule (+) ends to membranes; for example, linkage to the endoplasmic reticulum transmembrane protein STIM promotes microtubule-dependent extension of the tubular endoplasmic reticulum (discussed in Section 18.4; see Figure 18-27).

Other End-Binding Proteins Regulate Microtubule Disassembly

Mechanisms also exist for enhancing the disassembly of microtubules. Although most of the regulation of microtubule dynamics appears to happen at the (+) end, in some situations, such as in mitosis, it can occur at both ends.

EXPERIMENTAL FIGURE 18-14 The +TIP protein EB1 associates dynamically with the (+) ends of microtubules. (a) A cultured cell stained with antibodies to tubulin (red) and the +TIP protein EB1 (green). EB1 is enriched in the region of the microtubule (+) end. (b) Edge of a living cell expressing EB3-GFP (green) and mCherry-α-tubulin (red). EB3, which is closely related to EB1, is found at the ends of some microtubules. (c) EB3-GFP selectively associates with growing microtubules as seen in this so-called "kymograph." In this figure, the dynamics of a single microtubule (red) and EB3 (green) in a live cell like that shown in (b) is followed by taking the same region of sequential frames from a movie and lining them up top to bottom. At

the top, one sees the start of the movie with the microtubule capped by EB3. Moving down the figure, one can track the dynamics of the microtubule over time as it grows and shrinks. When the microtubule grows, it remains capped by EB3. When microtubule growth pauses or the microtubule shrinks, EB3 is no longer associated with the end, but it becomes reassociated when growth resumes. A diagrammatic summary of the microtubule dynamics is also shown. (d) A possible mechanism for how EB1 binds a growing microtubule and how other proteins can "hitchhike" on EB1. [Parts (a)–(c) Courtesy of Dr. A. Akhmanova, Cell Biology, Utrecht University, The Netherlands, and Dr. M. Steinmetz, Biomolecular Research, Paul Scherrer Institut, Villigen PSI, Switzerland.]

Various mechanisms for microtubule destabilization are known. One of these involves the kinesin-13 family of proteins. As we discuss in Section 18.4, most kinesins are molecular motors, but the kinesin-13 proteins are a distinct class that bind and curve the end of the tubulin protofilaments into the GDP-β-tubulin conformation. They then facilitate the removal of terminal tubulin dimers, thereby greatly enhancing the frequency of catastrophes

(Figure 18-15a). They act catalytically in the sense that they need to hydrolyze ATP to sequentially remove terminal tubulin dimers.

Another protein, known as Op18/stathmin, also enhances the rate of catastrophes. It was originally identified as a protein highly overexpressed in certain cancers; hence part of its name (Oncoprotein 18). Op18/stathmin is a small protein that binds two tubulin dimers in a curved, GDP-β-tubulin-like

FIGURE 18-15 Proteins that destabilize the ends of microtubules. (a) A member of the kinesin-13 family enriched at microtubule ends can enhance the disassembly of that end. (Although depolymerization of the (+) end is shown, kinesin-13 can also depolymerize the (-) end.) These proteins are ATPases, and ATP enhances their activity by dissociating them from the $\alpha\beta$ -tubulin dimer. (b) Stathmin binds selectively to curved protofilaments and enhances their dissociation from a microtubule end. Stathmin's activity is inhibited by phosphorylation.

conformation (Figure 18-15b). It may function by enhancing the hydrolysis of the GTP in the terminal tubulin dimer and aiding in its dissociation from the end of the microtubule. As might be expected for a regulator of microtubule ends, it is subject to negative regulation by phosphorylation by a large variety of kinases. In fact, it has been found that Op18/stathmin is inactivated by phosphorylation near the leading edge of motile cells, which contributes to preferential growth of microtubules toward the front of the cell.

KEY CONCEPTS of Section 18.3

Regulation of Microtubule Structure and Dynamics

- Microtubules can be stabilized by side-binding microtubule-associated proteins (MAPs) (see Figure 18-13).
- Some MAPs, called +TIPs, bind selectively to growing (+) ends of microtubules and can alter the dynamic properties of the microtubule or localize components to the searching (+) end of the microtubule (see Figure 18-14).
- Microtubule ends can be destabilized by some proteins, such as the kinesin-13 family of proteins and Op18/stathmin, to enhance the frequency of catastrophes (see Figure 18-15).

18.4 Kinesins and Dyneins: Microtubule-Based Motor Proteins

Organelles in cells are frequently transported distances of many micrometers along well-defined routes in the cytoplasm and delivered to particular intracellular locations. Diffusion alone cannot account for the rate, directionality, and destinations of such transport processes. Findings from early experiments with fish-scale pigment cells and nerve cells first demonstrated that microtubules function as tracks in the intracellular transport of various types of “cargo.”

As already discussed, polymerization and depolymerization of microtubules can do work using the energy provided by GTP hydrolysis. In addition, **motor proteins** move along microtubules powered by ATP hydrolysis. Two main families of motor proteins—**kinesins** and **dyneins**—are known to mediate transport along microtubules. In this section we discuss how these motor proteins work and the roles they perform in interphase cells. In subsequent sections, we discuss their functions in cilia and flagella, and in mitosis.

Organelles in Axons Are Transported Along Microtubules in Both Directions

A neuron must constantly supply new materials—proteins and membranes—to an axon terminal to replenish those lost in the exocytosis of neurotransmitters at the junction (synapse) with another cell (Chapter 22). Because proteins and membranes are primarily synthesized in the cell body, these materials must be transported down the axon, which can be as long as a meter in some neurons, to the synaptic region. This movement of materials is accomplished on microtubules, which are all oriented with their (+) ends toward the axon terminal (see Figure 18-5e).

The results of classic pulse-chase experiments, in which radioactive precursors were microinjected into the dorsal-root ganglia near the spinal cord and then tracked along their nerve axons, showed that **axonal transport** occurs from the cell body down the axon. Other experiments showed transport can also occur in the reverse direction, i.e., toward the cell body. **Anterograde** transport proceeds from the cell body to the synaptic terminals and is associated with axonal growth and the delivery of synaptic vesicles. In the opposite, **retrograde**, direction, “old” membranes from the synaptic terminals move along the axon rapidly toward the cell body, where they may be degraded in lysosomes. Findings from such experiments also revealed that different materials move at different speeds (Figure 18-16). The fastest-moving material, consisting of membrane-limited vesicles, has a velocity of about $3 \mu\text{m/s}$, or 250 mm/day —requiring about four days to travel from a cell body in your back down an axon that terminates in your big toe. The slowest-moving material, comprising tubulin subunits and neurofilaments (the intermediate filaments found in neurons), moves only a fraction of a millimeter per day. Organelles such as mitochondria move down the axon at an intermediate rate.

EXPERIMENTAL FIGURE 18-16 The rate of axonal transport in vivo can be determined by radiolabeling and gel electrophoresis.

The cell bodies of neurons in the sciatic nerve are located in dorsal-root ganglia (near the spinal cord). Radioactive amino acids injected into these ganglia in experimental animals are incorporated into newly synthesized proteins, which are then transported down the axon to the synapse. Animals are sacrificed at various times after injection and the dissected sciatic nerve is cut into small segments to see how far radioactively labeled proteins have been transported; these proteins can be identified after gel electrophoresis and autoradiography. The red, blue, and purple dots represent groups of proteins that are transported down the axon at different rates, red most rapidly, purple least rapidly.

Neurobiologists have long made extensive use of the squid giant axon for studying organelle movement along microtubules. Involved in regulating the squid's water propulsion system, the aptly named giant axon can be up to 1 mm in diameter, which is about 100 times wider than the average mammalian axon. Moreover, squeezing the axon like a tube of toothpaste results in the extrusion of the cytoplasm (also known as axoplasm), which can then be observed by video microscopy. The movement of vesicles along microtubules in this cell-free system requires ATP, its rate is similar to that of fast axonal transport in intact cells, and it can proceed in both the anterograde and the retrograde directions (Figure 18-17a). Electron microscopy of the same region of the axon cytoplasm reveals organelles attached to individual microtu-

bules (Figure 18-17b). These pioneering in vitro experiments established definitively that organelles move along individual microtubules and that their movement requires ATP.

Findings from experiments in which neurofilaments tagged with green fluorescent protein (GFP) were injected into cultured cells suggest that neurofilaments pause frequently as they move down an axon. Although the peak velocity of neurofilaments is similar to that of fast-moving vesicles, their numerous pauses lower the average rate of transport. These findings suggest that there is no fundamental difference between fast and slow axonal transport, although why neurofilament transport stops periodically is unknown.

Kinesin-1 Powers Anterograde Transport of Vesicles Down Axons Toward the (+) End of Microtubules

The protein responsible for anterograde organelle transport was first purified from axonal extracts. Researchers found that by mixing three components—purified organelles from squid axons, an organelle-free cytoplasmic axonal extract, and taxol-stabilized microtubules—organelles could be seen moving on the microtubules in an ATP-dependent manner. However, if they omitted the axonal extract, the organelles neither bound nor moved along the microtubules, suggesting that the extract contributes a protein that both attaches organelles to microtubules and transports them along it—i.e., a motor protein. The strategy for purifying the motor protein was based on additional observations of organelles moving on microtubules. It was known that if ATP was hydrolyzed to ADP, the organelles fell off the microtubules. However, if the nonhydrolyzable ATP analog AMPPNP was added, organelles remained associated with microtubules but did not move. This suggested that the motor linked the organelles to the microtubules very tightly in the presence of AMPPNP but then was released from the microtubule when the AMPPNP was replaced by ATP and its subsequent hydrolysis to ADP. Researchers used this clue to purify the motor.

Kinesin-1 isolated from squid giant axons is a dimer of two heavy chains, each associated with a light chain, with a total molecular weight of about 380,000. The molecule comprises a pair of globular *head domains* connected by a short flexible *linker domain* to a long *central stalk* and terminating in a pair of small globular *tail domains*, which associate with the light chains (Figure 18-18). Each domain carries out a particular function: the head domain binds microtubules and ATP and is responsible for the motor activity of kinesin; the linker domain is critical for forward motility; the stalk domain is involved in dimerization of the two heavy chains; and the tail domain is responsible for binding to receptors on the membrane of cargoes.

Kinesin-1-dependent movement of vesicles can be tracked by in vitro motility assays similar to those used to study myosin-dependent movements (see Figure 17-23). In one type of assay, a vesicle or a plastic bead coated with kinesin-1 is added to a glass slide along with a preparation of stabilized microtubules.

EXPERIMENTAL FIGURE 18-17 DIC microscopy demonstrates microtubule-based vesicle transport in vitro. (a) The cytoplasm was squeezed from a squid giant axon with a roller onto a glass coverslip. After buffer containing ATP was added to the preparation, it was viewed by differential interference contrast (DIC) microscopy, and the images were recorded on videotape. In the sequential images shown, the two organelles indicated by open and solid triangles move in opposite directions (indicated by colored arrows) along the same filament, pass each other, and continue in their original directions.

Elapsed time in seconds appears at the upper-right corner of each video frame. (b) A region of cytoplasm similar to that shown in part (a) was freeze-dried, rotary shadowed with platinum, and viewed in the electron microscope. Two large structures attached to one microtubule are visible; these structures presumably are small vesicles that were moving along the microtubule when the preparation was frozen. [See B. J. Schnapp et al., 1985, *Cell* **40**:455; courtesy of B. J. Schnapp, R. D. Vale, M. P. Sheetz, and T. S. Reese.]

FIGURE 18-18 Structure of kinesin-1. (a) Representation of kinesin-1 showing its two intertwined heavy chains, each with a motor domain in the head region. Each head is attached to the coiled-coil stalk by a flexible linker domain. Two light chains associate with the tail of the heavy chain. (b) X-ray structure of the kinesin heads with the microtubule-binding and nucleotide-binding sites (containing ADP) indicated, including the linkers and the beginning of the stalk region. VIDEO: Kinesin-1-Driven Transport of Vesicles Along Microtubules in Vitro

FIGURE 18-19 Model of kinesin-1-catalyzed vesicle transport.

Kinesin-1 molecules, attached to receptors on the vesicle surface, transport the vesicles from the (–) end to the (+) end of a stationary microtubule. ATP is required for movement. [Adapted from R. D. Vale et al., 1985, *Cell* 40:559, and T. Schroer et al., 1988, *J. Cell Biol.* 107:1785.]

In the presence of ATP, the beads can be observed microscopically to move along a microtubule in one direction. Researchers found that the beads coated with kinesin-1 always moved from the (–) to the (+) end of a microtubule (Figure 18-19). Thus kinesin-1 is a (+) end-directed microtubule motor protein, and additional evidence shows that it mediates anterograde axonal transport.

Kinesins Form a Large Protein Family with Diverse Functions

Following the discovery of kinesin-1, a number of proteins with similar motor domains were identified both in genetic screens and using molecular biology approaches. There are now 14 known classes of kinesins in animals, defined as sharing amino acid sequence homology with the motor domain of

kinesin-1. Proteins of the kinesin superfamily are encoded by about 45 genes in the human genome. Although the functions of all of these proteins have not yet been elucidated, some of the best-studied kinesins are involved in processes such as organelle, mRNA, and chromosome transport, microtubule sliding, and microtubule depolymerization.

As with the different classes of myosin motors, in the various kinesin families the conserved motor domain is fused to a variety of class-specific nonmotor domains (Figure 18-20). Whereas kinesin-1 has two identical heavy chains and two identical light chains, members of the kinesin-2 family (also

FIGURE 18-20 Structure and function of selected members of the kinesin superfamily. Kinesin-1, which includes the original kinesin isolated from squid axons, is a (+) end-directed microtubule motor involved in organelle transport. The kinesin-2 family has two different, but closely related, heavy chains, and a third cargo-binding subunit; this class also transports organelles in a (+) end-directed manner. The kinesin-5 family has four heavy chains assembled in a bipolar manner to interact with two antiparallel microtubules and also move toward the (+) end. Kinesin-13 family members have the motor domain in the middle of their heavy chains and do not have motor activity but they do destabilize microtubule ends (see also Figure 18-15a). Additional kinesin family members are mentioned in the text. Different kinesins have been given many different names; we use the unified nomenclature described in C. J. Lawrence et al., 2004, *J. Cell Biol.* 167:19–22. [Diagrams modified from R. D. Vale, 2003, *Cell* 112:467.]

involved in organelle transport) have two different related heavy-chain motor domains and a third polypeptide that associates with the tail and binds cargo. Members of the bipolar kinesin-5 family have four heavy chains, forming bipolar motors that can cross-link antiparallel microtubules and, by walking toward the (+) end of each microtubule, slide them past each other. The kinesin-14 motors are the only known class to move toward the (–) end of a microtubule; this class functions in mitosis. Yet another type, the kinesin-13 family, has two subunits but with the conserved kinesin domain in the middle of the polypeptide. Kinesin-13 proteins do not have motor activity, but recall that these are special ATP-hydrolyzing proteins that can enhance the depolymerization of microtubule ends (see Figure 18-15).

Kinesin-1 Is a Highly Processive Motor

How does kinesin-1 move down a microtubule? Optical trap and fluorescent-labeling techniques similar to those used to characterize myosin (see Figures 17-28, 17-29, and 17-30) have been used to study how kinesin-1 moves down a microtubule and how ATP hydrolysis is converted into mechanical work. Such experiments demonstrate that it is a very processive motor—taking hundreds of steps walking hand over hand down a microtubule without dissociating. During this process, the double-headed molecule takes 8-nm steps from one tubulin dimer to the next, tracking down the same protofilament in the microtubule. This entails each *individual* head taking 16-nm steps. The two heads work in a highly coordinated manner so that one is always attached to the microtubule.

The ATP cycle of kinesin-1 movement is most easily understood by first considering the cycle just after the motor has taken a step (Figure 8-21a). At this point the motor has a nucleotide-free leading head, under which conditions it is strongly bound to a tubulin dimer in a protofilament, and an ADP-bound trailing head that is weakly associated with the protofilament. ATP then binds to the leading head (Figure 18-21a, step 1) and this binding induces a conformational change in the linker domain so that instead of pointing backwards, it swings forward and “docks” into its associated head. This swinging motion results in the linker domain rotating forward and, because it is attached to the trailing head, it swings the trailing head—like throwing a ballet dancer—into position to become the leading head (Figure 18-21a, step 2). The new leading head finds the next binding site on the microtubule (Figure 18-21a, step 3 and Figure 18-21b). The binding of the leading head to the microtubule induces the leading head to release ADP while the trailing head hydrolyzes ATP to ADP and P_i , releasing P_i (Figure 18-21a, step 4). ATP can now bind to the leading head to repeat the cycle and allow the protein to take another step down the microtubule. Two features of this cycle ensure that one head is always firmly bound to the microtubule. First, the head domain binds tightly to the microtubule in the nucleotide-free, ATP and

ADP+ P_i states, but weakly in the ADP state. Second, the two heads communicate—when the leading head binds the microtubule and releases ADP, it is converted from a weak to a tight binding state. This message is communicated to the ATP-bound trailing head, tightly associated with the microtubule. The trailing head is stimulated to hydrolyze ATP, releasing P_i and converting to a weak binding state. Because this cycle requires one head to always be firmly attached to a tubulin dimer in a protofilament, kinesin-1 can take thousands of steps along a microtubule without disassociating, and is therefore exceptionally processive as it moves down a microtubule.

When the x-ray structure of the kinesin head was determined, it revealed a major surprise—the catalytic core has the same overall structure as myosin’s (Figure 18-22)! This occurs despite the fact that there is no amino acid sequence conservation between the two proteins, arguing strongly that convergent evolution twice generated a fold that can utilize the hydrolysis of ATP to generate work. Moreover, the same type of three-dimensional structure is seen in small GTP-binding proteins, such as Ras, that undergo a conformational change on GTP hydrolysis (see Figure 15-7).

Dynein Motors Transport Organelles Toward the (–) End of Microtubules

In addition to kinesin motors, which primarily mediate anterograde (+) end-directed transport of organelles, cells use another motor, *cytoplasmic dynein*, to transport organelles in a retrograde fashion toward the (–) end of microtubules. This motor protein is very large, consisting of two large (>500 kDa), two intermediate, and two small subunits. It is responsible for the ATP-dependent retrograde transport of organelles toward the (–) ends of microtubules in axons, as well as many other functions we consider in the next sections. Compared to myosins and kinesins, the family of dynein-related proteins is not very diverse.

Like kinesin-1, cytoplasmic dynein is a two-headed molecule, built around two identical or nearly identical heavy chains. However, because of the enormous size of the motor domain, dynein has been less well characterized in terms of its mechanochemical activity. A single dynein heavy chain consists of a number of distinct domains (Figure 18-23). It consists of the *stem*, to which the other dynein subunits bind and which associates with its cargo through dynactin (see below). The next part of the heavy chain is a *linker* that, as we discuss later, plays a critical role during ATP-dependent motor activity. A large part of the heavy chain makes up the *head* containing the AAA ATPase domain, consisting of six repeats that assemble into a flowerlike structure, within which lies the ATPase activity. Embedded between the fourth and fifth AAA repeats is the *stalk*, which protrudes from the structure and contains the microtubule-binding region. Electron microscopy, combined with recently acquired x-ray images of the structure of a dynein heavy chain, provide a

FIGURE 18-21 Kinesin-1 uses ATP to “walk” down a microtubule.

(a) In this diagram, the two kinesin heads are shown with differently colored linker domains (yellow and red) to distinguish them. The cycle is shown starting after kinesin has taken a step, with the leading head tightly bound to the microtubule and not bound by any nucleotide, while the trailing head is weakly bound to the microtubule and has ADP bound. The leading head then binds ATP (step **1**), which induces a conformational change that causes the yellow linker region to swing forward and dock into its associated head domain, thereby thrusting the trailing head forward (step **2**). The new leading head now finds a binding site 16 nm down the microtubule, to which it binds weakly (step **3**). The leading head now releases ADP and binds tightly to the

microtubule, which induces the trailing head to hydrolyze ATP to ADP and P_i (step **4**). P_i is released and the trailing head is converted into a weak binding state, and also releases the docked linker domain. The cycle now repeats itself for another step. (b) Structural model of two kinesin heads (purple) bound to a protofilament in a microtubule. The trailing head, at left, has bound ATP and has thrust the other head into the leading position. Notice how the linker domain (yellow) is docked into the trailing head, whereas the linker domain (red) of the leading head is still free. [Part (a) modified from R. D. Vale and R. A. Milligan, 2000, *Science* **288**:88. Part (b) based on E. P. Sablin and R. J. Fletterick, 2004, *J. Biol. Chem.* **279**:15707–15710.]

FIGURE 18-22 Convergent structural evolution of the ATP-binding cores of myosin and kinesin heads.

The common catalytic cores of myosin and kinesin are shown in yellow, the nucleotide in red, and the lever arm (for myosin-II) and linker domain (for kinesin-1) in light purple. [Modified from R. D. Vale and R. A. Milligan, 2000, *Science* **288**:88.]

glimpse of how dynein might work. Before a power stroke, the stem is attached to the linker that lies across the AAA domain and associates with the first and third AAA repeats (Figure 18-24a and b, left panels). Upon ATP binding and hydrolysis, the AAA ring changes conformation slightly and the linker domain becomes associated with the first and fifth

AAA repeat. This conformational change rotates the molecule to bring the stem and stalk closer, resulting in the transport of cargo toward the (–) end of the microtubule (Figure 18-24a and b, right panels).

Unlike kinesin-1, cytoplasmic dynein cannot mediate cargo transport by itself. Rather, dynein-related transport generally requires *dynactin*, a large protein complex that both links dynein to its cargo and regulates its activity (Figure 18-25). Dynactin consists of 11 different types of subunits, functionally organized into two domains. One domain is built around eight copies of the actin-related protein Arp1, which assembles into a short filament. The end corresponding to the (+) end of this filament is capped by CapZ, the same capping protein that binds the (+) end of an actin filament (see Figure 17-12); a number of subunits are associated with the (–) end. This Arp1-containing domain is responsible for binding cargo. The second domain of dynactin consists of a long protein called p150^{Glued}, which contains the dynein-binding site and also has a microtubule-binding site at one end. Holding the two dynactin domains together is a protein called *dynamitin*—so named because when it is overexpressed, it dissociates (or “blows apart”) the two domains, making a nonfunctional complex. This feature has been very useful experimentally because it has allowed researchers to identify processes that are dependent on dynein-dynactin, which are disrupted in cells overexpressing dynamitin. The microtubule-binding site in dynactin allows it to hold loosely onto a microtubule as the dynein motor moves down the microtubule (Figure 18-25c), helping the dynactin-dynein complex remain associated with the microtubule. Thus, the major functions of dynactin are to bind cargo and to make dynein more processive.

How is dynein regulated? It has been found that the dynactin p150^{Glued} subunit binds +TIP EB1, allowing dynein to be associated with the growing (+) end of microtubules. Why would dynein associate with microtubule (+) ends if it is a (–) end–directed motor? Recent work suggests that when dynein is associated with the (+) end of microtubules

FIGURE 18-23 The domain structure of cytoplasmic dynein.

(a) The dynein heavy chain, consisting of over 4000 amino acid residues, has several distinct domains. Following the stem and linker domains are six AAA repeats (peach, numbered 1–6), with the stalk and its microtubule-binding domain between repeats 4 and 5. The protein ends in an α -helical domain that supports the stalk (b). The six AAA repeats assume a structure like petals on a flower. Emerging from this is a coiled-coil stalk domain with a microtubule-binding site at the end. A number of additional subunits associate with the stem region and link dynein to cargo through dynactin. [Modified from R. D. Vale, 2003, *Cell* **112**:467.]

FIGURE 18-24 The power stroke of dynein. (a) Multiple images of purified single-headed dynein molecules in their pre-stroke and post-stroke states were recorded in an electron microscope and then averaged. The image at left shows dynein in the ADP+P state, which represents the pre-stroke state, and the image at right shows it in a nucleotide-free post-stroke state. (b) A comparison of the images

combined with recently acquired structural data shows that the force-generation mechanism involves a change in orientation of the head relative to the stem, causing a movement of the microtubule-binding stalk. [Part (a) modified from S. A. Burgess et al., 2003, *Nature* **421**:715; courtesy of S. A. Burgess. Part (b) based on the dynein structure in A. P. Carter et al., 2011, *Science* **331**:1159–1165.]

via the dynactin-EB1 interaction, it is held in an inactive conformation. When the growing microtubule reaches the cell cortex, the inactive dynein and dynactin encounter an activator localized there. The dynein now becomes active, associating with the cortex and pulling on the microtubule that delivered it to the cortex! This mechanism has been shown to help orient the mitotic spindle in yeast, and likely applies to other situations as well.

 In addition to the regulatory p150^{Glued} subunit of dynactin, additional regulators of dynein activity exist. A

group of proteins, two of which are LIS1 and NudE, are involved in regulating the activity of dynein. NudE links the dynein intermediate and light chains to LIS1 (Figure 18-26a). LIS1 then interacts with the ATPase domain of dynein to lengthen the power stroke, making the motor more processive under conditions of high load. Defects in LIS1 cause the fatal disease Miller-Dieker lissencephaly (from where the protein got its name); lissencephaly means “smooth brain,” as cortical folds and grooves are lacking in the brains of patients with this condition (Figure 18-26b). Mutations in LIS1 result in defects in both neuronal mitoses and migration from

FIGURE 18-25 The dynactin complex linking dynein to cargo. (a) One domain of the complex binds cargo and is built around a short filament made up of about eight subunits of the actin-related protein Arp1 capped by CapZ. Another domain consists of the protein p150^{Glued}, which has a microtubule-binding site on its distal end and is also involved in attaching cytoplasmic dynein to the complex. Dynamitin holds the two parts of the dynactin complex together. (b) Electron

micrograph of a metal replica of the dynactin complex isolated from brain. The Arp1 minifilament (purple) and the dynamitin/p150^{Glued} side arm (teal) are highlighted. the ventricular zone to the cortical plate in early development, resulting in the smooth-brain phenotype and defects in mental development as well as many other abnormalities. ■

Kinesins and Dyneins Cooperate in the Transport of Organelles Throughout the Cell

Both dynein and kinesin family members play important roles in the microtubule-dependent organization of organelles in

cells (Figure 18-27). Because the orientation of microtubules is fixed by the MTOC, the direction of transport—toward or away from the cell center—depends on the motor protein. For example, the Golgi apparatus collects in the vicinity of the centrosome, where the (–) ends of microtubules lie, and is driven there by dynein-dynactin. In addition, secretory cargo emerging from the endoplasmic reticulum is transported to the Golgi by dynein-dynactin. Conversely, the endoplasmic reticulum is spread throughout the cytoplasm and

VIDEO: Transport of Vesicles Along Microtubules from the Endoplasmic Reticulum to the Golgi

FIGURE 18-27 Organelle transport by microtubule motors. Cytoplasmic dyneins (red) mediate retrograde transport of organelles toward the (–) end of microtubules (cell center); kinesins (purple) mediate anterograde transport toward the (+) end (cell periphery). Most organelles have one or more microtubule-based motors associated with them. It should be noted that the association of motors with organelles varies by cell type, so some of these associations may not exist in all cells, whereas others not shown here also exist. ERGIC = ER-to-Golgi intermediate compartment.

VIDEO: Aggregation and Dispersion of Pigment Granules in Fish Melanophores

FIGURE 18-28 Movement of pigment granules in frog melanophores. (a) Diagram of the microtubule-based reorganization of melanosomes according to the level of cAMP. Melanosomes are aggregated by cytoplasmic dynein and dispersed by kinesin-2. (b) Visualization of melanosomes in the dispersed state as seen by immunofluorescence microscopy for microtubules (green), the DNA in the nucleus (blue), and pigment granules (red). [Part (a) modified from V. Gelfand and S. Rogers, <http://www.cellbio.duke.edu/kinesin/Pigment-aggregation.html>. Part (b) from S. Rogers, www.itg.uiuc.edu/exhibits/gallery/]

is transported there by kinesin-1, which moves toward the peripheral (+) ends of microtubules. Some organelles of the endocytic pathway are associated with dynein-dynactin, including late endosomes and lysosomes. Kinesins have been shown to transport mitochondria, as well as nonmembranous cargo such as specific mRNAs encoding proteins that need to be localized during development.

We have seen how kinesin-1 transports organelles in an anterograde fashion down axons. What happens to the motor when it gets to the end of the axon? The answer is that it is carried back in a retrograde fashion on organelles transported by cytoplasmic dynein. Thus kinesin-1 and dynein can associate with the same organelle and a mechanism must exist that turns one motor off while activating the other, although such mechanisms are not yet fully understood.

Much of what we know about the regulation of microtubule-based organelle transport comes from studies using fish (e.g., angelfish) or frog melanophores. Melanophores are cells of the vertebrate skin that contain hundreds of dark melanin-filled pigment granules called melanosomes. Melanophores either have their pigment granules dispersed, in which case they make the skin darker, or aggregated at the center, which makes the skin paler (Figure 18-28). These changes in skin color, mediated by neurotransmitters in the fish and regulated by hormones in the frog, serve to camouflage the fish and enhance social interactions in the frog. The movement of the granules is mediated by changes in intracellular cAMP and is dependent on microtubules. Studies investigating which motors are involved have shown that pigment granule dispersion requires kinesin-2, whereas aggregation requires cytoplasmic dynein-dynactin. The first hints of how these activities might be coordinated came from the finding that overexpression of dynactin inhibited granule transport in both directions. This surprising result was explained when it was found that dynactin binds not only to cytoplasmic dynein but also to kinesin-2—and may coordinate the activity of the two motors.

The association of dynein and kinesin-2 with the same organelle is not limited to melanosomes; it has recently been suggested that these motors may cooperate to appropriately localize late endosomes/lysosomes and mitochondria in some cells. Thus the concept that organelles can have a number of distinct motors associated with them is not the exception, but an emerging theme.

Tubulin Modifications Distinguish Different Microtubules and Their Accessibility to Motors

The stability and functions of different classes of microtubules are influenced by post-translational modifications. Although multiple types of modification have been detected, we restrict our discussion to those that are the best understood—lysine acetylation, detyrosylation, polyglutamylation, and polyglycylation (Figure 18-29a)—and their functional consequences.

Two of these modifications are only found on α -tubulin and are absent from β -tubulin. The first is the *acetylation* of the ϵ -amino group of a specific lysine residue of α -tubulin that lies on the inside of the microtubule; microtubules with this acetylated lysine are found in stable microtubule structures like centrioles, basal bodies, and primary cilia (primary cilia are discussed in Section 18.5). Indeed, cells unable to acetylate tubulin have defective primary cilia, whereas cells in which acetylation cannot be removed result in unusually stable primary cilia. The second modification of α -tubulin relates to its C-terminal tyrosine. This tyrosine can be specifically removed by a carboxypeptidase that only functions when bound to the surface of microtubules, where it sequentially removes the C-terminal tyrosines off α -tubulin subunits. These *detyrosylated* microtubules are more stable, as they are more resistant to depolymerization by the kinesin-13 family of depolymerizers. Moreover, in migrating cells, these more stable microtubules are generally oriented toward the front of the cell. When a

(a)

EXPERIMENTAL FIGURE 18-29 Post-translational modifications of tubulin affect the stability and function of microtubules.

(a) Structure of α - and β -tubulin showing the sites of lysine acetylation on the inner surface of the microtubule, and polyglutamylation, polyglycylation, and detyrosylation on the outer surface. Note that polyglutamylation and polyglycylation are believed to be mutually exclusive, so they would not normally occur at the same time.

stable microtubule depolymerizes, the α -tubulin subunit of the $\alpha\beta$ -dimer has the C-terminal tyrosine added back by a tyrosine ligase that only acts on soluble tubulin, and the $\alpha\beta$ -tubulin dimer can now be used for a new microtubule.

The C-terminal regions of both α - and β -tubulin are very rich in glutamic acid residues, and specific enzymes can modify these residues. Again, these modifications occur only after assembly of the microtubule. The tails can be modified by *polyglutamylation*, where a chain of glutamic acid residues is linked to a specific glutamate residue, or subject to *polyglycylation*, where a chain of glycine residues is added to a different glutamic residue. At present it is believed that these two modifications may be mutually exclusive, so that if a tubulin subunit is modified by polyglycylation, it is protected from polyglutamylation, and vice versa. Like the other modifications, polyglutamylation can enhance microtubule stability.

These post-translational modifications of tubulin not only affect microtubule stability, but they can also affect the ability of molecular motors to interact with microtubules (Figure 18-29b). Kinesin-1 associates preferentially with detyrosylated and acetylated microtubules, which may be important in recruiting this motor for axonal transport in neurons. As we mentioned in Figure 18-5e, neurons have different microtubule organizations in their dendrites and axons. The microtubules in the axon are stabilized by acetylation and detyrosylation and this allows kinesin-1 to preferentially associate with them for axonal transport. Polyglutamylation has a key role in the beating of cilia and flagella, which we discuss in the next section.

(b)

(b) Detyrosylated microtubules are preferentially oriented toward the leading edge of a moving cell. A cell migrating toward the right is stained for total microtubules (red) and detyrosylated microtubules (green). The resulting merge shows the detyrosylated microtubules enriched toward the front of the cell in yellow, which is a combination of red and green. [(a) Modified from J. W. Hamond, D. Cai, and K. J. Verhey, 2008, *Curr. Opin. Cell Biol.* **20**:71–76. (b) Courtesy of Greg Gundersen.]

The research elucidating the effects of post-translational modifications of tubulin on microtubule function and microtubule-based motors is all quite recent; we can expect future studies to reveal multiple “codes” that distinguish different classes of microtubules and specialize them for specific functions.

KEY CONCEPTS of Section 18.4

Kinesins and Dyneins: Microtubule-Based Motor Proteins

- Kinesin-1 is a microtubule (+) end-directed ATP-dependent motor that transports membrane-bound organelles (see Figure 18-19).
- Kinesin-1 consists of two heavy chains, each with an N-terminal motor domain, and two light chains that associate with cargo (see Figure 18-18).
- The kinesin superfamily includes motors that function in interphase and mitotic cells, transporting organelles and sliding antiparallel microtubules past one another. The superfamily includes one class, kinesin-13, that is not motile but destabilizes microtubule ends (see Figure 18-20).
- Kinesin-1 is a highly processive motor because it coordinates ATP hydrolysis between its two heads so that one head is always firmly bound to a microtubule (see Figure 18-21).

- Cytoplasmic dynein is a microtubule (–) end-directed ATP-dependent motor that associates with the dynactin complex to transport cargo (see Figure 18-25).
- Kinesins and dyneins associate with many different organelles to organize their location in cells (see Figure 18-27).
- Post-translational modifications of tubulin can affect microtubule stability and regulate their ability to interact with microtubule-based motors.

18.5 Cilia and Flagella: Microtubule-Based Surface Structures

Cilia and flagella are related microtubule-based and membrane-bound extensions that project from many protozoa and most animal cells. Abundant motile cilia are found on the surface of specific epithelia, such as those that line the trachea, where they beat in an orchestrated wavelike fashion to move fluids. Animal-cell flagella, which are longer than cilia but have a very similar structure, can propel a cell, such as sperm,

FIGURE 18-30 Structural organization of cilia and flagella.

(a) Cilia and flagella are assembled from a basal body, a structure built around nine linked triplet microtubules. Continuous with the A and B microtubules of the basal body are the A and B tubules of the axoneme—the membrane-bound core of the cilium or flagellum. Between the basal body and axoneme is the transitional zone. The diagram and accompanying transverse sections of the basal body, transitional zone, and axoneme show their intricate structures. (b) Thin section of a transverse section of a cilium (with plasma membrane removed) with a diagram to show the identity of the structures. [Part (a) modified from S. K. Dutcher, 2001, *Curr. Opin. Cell Biol.* 13:49–54; courtesy of S. Dutcher. Part (b) courtesy of L. Tilney.]

through liquid. Cilia and flagella contain many different microtubule-based motors: axonemal dyneins are responsible for the beating of flagella and cilia, whereas kinesin-2 and cytoplasmic dynein are responsible for flagella and cilia assembly and turnover.

Eukaryotic Cilia and Flagella Contain Long Doublet Microtubules Bridged by Dynein Motors

Cilia and flagella range in length from a few micrometers to more than 2 mm for some insect sperm flagella. They possess a central bundle of microtubules, called the **axoneme**, which consists of a so-called 9 + 2 arrangement of nine doublet

microtubules surrounding a central pair of singlet, yet ultrastructurally distinct, microtubules (Figure 18-30a, b). Each of the nine outer doublets consists of an A microtubule with 13 protofilaments and a B microtubule with 10 protofilaments (see Figure 18-4). All the microtubules in cilia and flagella have the same polarity: the (+) ends are located at the distal tip. At its point of attachment in the cell, the axoneme connects with the **basal body**, a complicated structure containing nine triplet microtubules (see Figure 18-30a).

The structure of the axoneme is held together by three sets of protein cross-links (see Figure 18-30b). The two central singlet microtubules are connected to each other by periodic bridges, like rungs on a ladder. A second set of linkers, composed of the protein *nexin*, joins adjacent outer doublet microtubules to each other. *Radial spokes* project from each A tubule of the outer doublets toward the central pair.

The major motor protein present in cilia and flagella is *axonemal dynein*, a large, multisubunit protein related to cytoplasmic dynein. Two rows of dynein motors are attached periodically down the length of each A tubule of the outer doublet microtubules; these are called the *inner-arm* and *outer-arm* dyneins (see Figure 18-30b). It is these dynein motors interacting with the B tubule in the adjacent doublet that bring about cilia and flagella bending.

Ciliary and Flagellar Beating Are Produced by Controlled Sliding of Outer Doublet Microtubules

Cilia and flagella are motile structures because activation of the axonemal dynein motors induces bending in them. A close examination of this motility using video microscopy reveals that a bend starts at the base of a cilium or flagellum and then propagates along the structure (Figure 18-31). A clue to how this occurs came from studies of isolated axonemes. In classic experiments, axonemes were gently treated with a protease that cleaves just the *nexin* links. When ATP was added to the treated axonemes, the doublet microtubules slid past one

EXPERIMENTAL FIGURE 18-31 Video microscopy shows flagellar movements that propel sperm and *Chlamydomonas* forward. In both cases, the cells are moving to the left. (a) In the typical sperm flagellum, successive waves of bending originate at the base and are propagated out toward the tip; these waves push against the water and propel the cell forward. Captured in this multiple-exposure sequence, a bend at the base of the sperm in the first (top) frame has moved distally halfway along the flagellum by the last frame. A pair of gold beads on the flagellum are seen to slide apart as the bend moves through their region. (b) Beating of the two flagella on *Chlamydomonas* occurs in two stages, called the *effective stroke* (top three frames) and the *recovery stroke* (remaining frames). The effective stroke pulls the organism through the water. During the recovery stroke, a different wave of bending moves outward from the bases of the flagella, pushing the flagella along the surface of the cell until they reach the position to initiate another effective stroke. Beating commonly occurs 5–10 times per second. [Part (a) from C. Brokaw, 1991, *J. Cell Biol.* 114(6): cover photograph; courtesy of C. Brokaw. Part (b) courtesy of S. Goldstein.]

(b) Nexin links removed by protease

FIGURE 18-32 Cilia and flagella bending mediated by axonemal dynein. (a) Axonemal dynein attached to an A tubule of an outer doublet pulls on the B tubule of the adjacent tubule trying to move to the (-) end. Because the adjacent tubules are tethered by nexin, the force generated by dynein bends the cilium or flagellum. (b) Experimental evidence for the model in (a). When the nexin links are cleaved with a protease and ATP added to induce dynein activity, the microtubule doublets slide past one another. (c) Electron micrograph of two doublet microtubules in a protease-treated axoneme incubated with ATP. In the absence of cross-linking proteins, doublet microtubules slide excessively. The dynein arms can be seen projecting from A tubules and interacting with B tubules of the left microtubule doublet. [Part (a) Courtesy of Wallace Marshall; part (c) courtesy of P. Satir.]

another as dynein, attached to the A tubule of one doublet, “walked” down the B tubule of the adjacent doublet (Figure 18-32b, c). In an axoneme with intact nexin links, the action of dynein induces flagellar bending as the microtubule doublets are connected to one another (Figure 18-32a).

How specific subsets of dynein are activated and how a wave of activation is propagated down the axoneme are not yet fully understood, but post-translational modifications of tubulin may play a role. Recall from Section 18.4 that post-translational modifications of tubulin subunits can affect the interactions between microtubules and motor proteins. The B tubules of the outer axoneme doublets are often polyglutamylated, and this modification strongly affects the interaction of the inner-arm dynein with the B tubule. Since inner-arm dynein motors mainly affect the waveform of the ciliary beat, it is this aspect of ciliary function that is compromised in mutants unable to undergo polyglutamylation.

Intraflagellar Transport Moves Material up and down Cilia and Flagella

Although axonemal dynein is involved in bending flagella, another type of motility has been observed more recently. Careful examination of flagella on the biflagellate green alga *Chlamydomonas reinhardtii* revealed cytoplasmic particles moving at a constant speed of $\sim 2.5 \mu\text{m/s}$ toward the tip of the flagella (anterograde movement) and other particles moving at $\sim 4 \mu\text{m/s}$ from the tip to the base (retrograde movement). This transport is known as *intraflagellar transport (IFT)* and occurs in both cilia and flagella. Light and electron microscopy revealed that the particles move between the outer doublet microtubules and the plasma membrane (Figure 18-33). Analysis of algal mutants demonstrated that the anterograde movement is powered by kinesin-2 and the retrograde movement is powered by cytoplasmic dynein.

The anterograde and retrograde IFT particles transported in *Chlamydomonas* flagella have been isolated and their composition determined. They consist of two distinct protein complexes, called IFT complex A and IFT complex B. By analyzing the phenotypes of cells having mutations affecting complexes A or B, it has been found that complex B is necessary for anterograde IFT transport, whereas complex A is important for retrograde IFT transport. Despite this segregation of function, both complexes are transported in both directions. All the

FIGURE 18-33 Intraflagellar transport. (a) Particles are transported between the plasma membrane and the outer doublet microtubules. Transport of the particles to the tip is dependent on kinesin-2, whereas transport toward the base is mediated by

cytoplasmic dynein. (b) Thin-section electron micrograph shows IFT particles in a section of a *Chlamydomonas* flagellum. [Part (b) from J. L. Rosenbaum and G. B. Witman, 2003, *Nature Rev. Mol. Cell Biol.* 3:813–825.]

components of IFT particles have homologs in organisms containing cilia, such as nematodes, fruit flies, mice, and humans, but these particles are absent from the genomes of yeasts and plants that lack cilia, suggesting they are specific to IFT.

What is the function of IFT? Because all the microtubules have their growing (+) ends at the flagellar tip, this is the site at which new tubulin subunits and flagellar structural proteins are added. Moreover, even in cells with flagella of uniform length, the microtubules are turning over with assembly and disassembly occurring at the flagellar tips. In cells defective for kinesin-2, flagella shrink, suggesting that IFT transports new material to the tip for growth. Since IFT is a continually occurring process, what happens to the kinesin-2 molecules when they get to the tip, and where do the dynein motors come from to transport the particles retrogradely? Remarkably, dynein is carried to the tip as cargo on the anterograde-moving particles, powered by kinesin-2, and then kinesin-2 becomes cargo as the particles are transported back to the base by dynein.

Primary Cilia Are Sensory Organelles on Interphase Cells

Many vertebrate cells contain a solitary non-motile cilium, known as the *primary cilium*. The primary cilium is a stable structure that is much more resistant to drugs like colchicine

that disassemble most microtubules; after colchicine treatment the only remaining microtubules are found in the centrioles and the primary cilium (see Figure 18-12). Moreover, the tubulin in the primary cilium is highly acetylated, so using antibodies that specifically recognize acetylated α -tubulin readily identifies the single primary cilium on each interphase cell (Figure 18-34a).

Terminally differentiated and dividing cells in interphase contain primary cilia, and in the latter case the presence of the cilium is tied to the duplication cycle of the centrioles (discussed in Section 18.6), with the “older” centriole functioning as the basal body for the assembly of the cilium (Figure 18-34b).

The primary cilium is non-motile because it lacks the central pair of microtubules and dynein side arms (Figure 18-34c). Recent work has led to the discovery that the primary cilium is instead a sensory organelle, acting as the cell’s “antenna” by detecting extracellular signals. For example, the sense of smell is due to binding of odorants by receptors located in the primary cilium of olfactory sensory neurons in the nose (see Chapter 22). In another example, the rod and cone cells of the eye have a primary cilium with a greatly expanded tip to accommodate proteins involved in photoreception. The retinal protein opsin moves through the cilium at about 2000 molecules per minute, transported by kinesin-2 as part of the IFT system. Defects in this transport cause retinal degeneration.

FIGURE 18-34 Many interphase cells contain a non-motile primary cilium. Mol Cell Biol.* 12:222–234. (d) From G. Pazour et al., 2000, *J. Cell Biol.* 151:709–718.]

Defects in Primary Cilia Underlie Many Diseases

For many years the existence and function of the primary cilium was ignored. However, this situation has changed dramatically over the last decade as it has become appreciated that defects in intraflagellar transport result in the loss of primary cilia in mice (Figure 18-34d), and diseases have been traced to defects in primary cilia and IFT. One of the first clues came from the discovery that loss of a mammalian homolog of a *Chlamydomonas* IFT protein results in defects in the primary cilium and causes autosomal dominant polycystic kidney disease (ADPKD). It is believed that the primary cilia on the epithelial cells of the kidney collecting tubule act as mechanochemical sensors to measure the rate of fluid flow by the degree to which they are bent. In another example, patients with Bardet-Biedl syndrome have retinal degeneration, polydactyly (from the Greek for “many fingers”), and obesity; the syndrome can be caused by mutations in any one of 14 genes and has been traced to defects in the function of primary cilia. Many of these genes encode subunits of the BBsome, an octomeric complex that forms a coat with structural elements in common with COPI, COPII, and clathrin coats, and that traffics

membrane proteins to cilia. While defects in many of the BBsome components do not affect the structure of the primary cilium itself, they result in a lack of specific membrane receptors that are delivered to primary cilia through the interaction of the BBsome with the IFT apparatus. For example, the polydactyly seen in patients with Bardet-Biedl syndrome is due to a loss of localized Hedgehog signaling (see Chapter 16) in the primary cilium that is necessary for patterning during embryogenesis. ■

KEY CONCEPTS of Section 18.5

Cilia and Flagella: Microtubule-Based Surface Structures

- Motile cilia and flagella are microtubule-based cell-surface structures with a characteristic central pair of singlet microtubules and nine sets of outer doublet microtubules (see Figure 18-30).
- All cilia and flagella grow from basal bodies, structures with nine sets of outer triplet microtubules and closely related to centrioles.

- Axonemal dyneins attached to the A tubule on one doublet microtubule interact with the B tubule of another to bend cilia and flagella.
- Cilia and flagella have a mechanism, intraflagellar transport (IFT), to transport material to their tips by kinesin-2 and from the tip back to the base by cytoplasmic dynein. This transport regulates the function and length of cilia and flagella.
- Many cells have on their surface a single non-motile primary cilium that lacks the normal central pair of microtubules and dynein side arms of motile cilia. The primary cilium functions as a sensory organelle, with receptors for extracellular signals localized to its plasma membrane. Due to its sensory function, many diseases result from defects in receptor localization or in the structure of the primary cilium itself.

18.6 Mitosis

Of all the events that permit the existence and perpetuation of life, perhaps the most critical is the ability of cells to accurately duplicate and then faithfully segregate their chromosomes at each cell division. During the cell cycle, a highly regulated process discussed in Chapter 19, cells duplicate their chromosomes precisely once during a period known as S phase (for DNA synthesis phase). Once the individual chromosomes are duplicated, they are held together by proteins called *cohesins*. The cells then pass through a period called G₂ (for gap 2) before entering mitosis, the process by which the duplicated chromosomes are segregated to the daughter cells. This process has to be very precise—loss or gain of a chromosome can either be lethal to the cell (in which case it is often not detected) or cause severe complications for the cell. It is estimated that yeast only mis-segregates one of its 16 chromosomes every 100,000 cell divisions, which makes mitosis one of the most accurate processes in biology. To achieve this accuracy, it is essential for the process to be highly regulated such that it proceeds in an orderly series of steps and that errors are not made. The timing and mechanisms that ensure the fidelity of the process are closely regulated by the cell-cycle circuitry that we discuss in detail in Chapter 19. Here we limit our discussion of this circuitry as it applies to microtubules and the mechanics of mitosis.

Centrosomes Duplicate Early in the Cell Cycle in Preparation for Mitosis

In order to separate the chromosomes during mitosis, cells duplicate their MTOCs—their centrosomes—coordinately with the duplication of their chromosomes in S phase (Figure 18-35). The duplicated centrosomes separate and become the two spindle poles of the mitotic spindle. The number of centrosomes in animal cells has to be very carefully controlled. In fact, many tumor cells have more than two centrosomes, which contributes to genetic instability resulting from mis-segregation of chromosomes and hence **aneuploidy**

FIGURE 18-35 Relation of centrosome duplication to the cell cycle. After the pair of parent centrioles (green) separates slightly, a daughter centriole (blue) buds from each and elongates. By G₂, growth of the daughter centrioles is complete, but the two pairs remain within a single centrosomal complex. Early in mitosis, the centrosome splits, and each centriole pair migrates to opposite sides of the nucleus. The amount of pericentriolar material and the activity to nucleate microtubule assembly increases greatly in mitosis. In mitosis, these MTOCs are called spindle poles.

(unequal numbers of chromosomes). The reasons why aneuploidy results in cancer are discussed in detail in Chapter 24.

As cells enter mitosis, the activity of the two MTOCs—their ability to nucleate microtubules—increases greatly as they accumulate more pericentriolar material. Because the microtubules radiating from these two MTOCs now resemble stars, they are often called mitotic asters.

Mitosis Can Be Divided into Six Phases

Mitosis has been divided up into several stages for ease of description (Figure 18-36a), but in reality it is a continuous process. Here, we review the major events of each stage.

The first stage of mitosis, called **prophase**, is signaled by a number of coordinated and dramatic events. First, the interphase array of microtubules is replaced as the duplicated centrosomes become more active in microtubule nucleation. This provides two sites of assembly for dynamic microtubules, forming the mitotic asters. Additionally, the dynamics of the growing microtubules themselves increase, due to changes in the activities of +TIPs at their (+) ends. The two asters are then moved to opposite sides of the nucleus by the action of bipolar kinesin-5 motors (see Figure 18-20) that push the intermingling astral microtubules apart. The separated centrosomes will become the two poles of the **mitotic spindle**, the microtubule-based structure that separates chromosomes. Second, protein synthesis is switched from being CAP-dependent to CAP-independent (see Chapter 4, Figure 4-24), and the internal order of membrane systems, normally dependent on the interphase array of microtubules, is disassembled. In addition, endocytosis and exocytosis are halted, and the microfilament organization is generally rearranged to give rise to a rounded cell. In the nucleus, the nucleolus breaks down and

FIGURE 18-36 The stages of mitosis. (a) Upper panels show stages in cultured PtK2 cells stained blue for DNA and green for tubulin. Lower diagrams show the different stages and the events that occur in them. Mitosis is a continuous process, and it has simply been divided into stages for ease of description. (b) Parts of a condensed chromosome in mitosis. The duplicated chromosome has two sister chromatids (each is a single DNA duplex), held together by cohesins at a constricted region called the centromere. The centromere is also the site where the kinetochore forms, which makes attachments to the kinetochore microtubules. [Part (a) micrographs courtesy of T. Wittmann.]

chromosomes begin to condense. Cohesins holding together each pair of duplicated chromosomes, or **sister chromatids** as they are called at this stage, are degraded except at the centromeric region, where the two sister chromatids remain linked by intact cohesins (Figure 18-36b). Also during prophase, specialized structures called **kinetochores**, which will become sites of microtubule attachment, assemble at the centromeric region of each sister chromatid. As discussed in more detail in Chapter 19, all these events are coordinated by a rapid increase in the activity of the mitotic cyclin-CDK complex, which is a kinase that phosphorylates multiple proteins.

The next stage of mitosis, **prometaphase**, is initiated by the breakdown of the nuclear envelope and nuclear pores, and disassembly of the lamin-based nuclear lamina. Microtubules assembled from the spindle poles search and “capture”

chromosome pairs by associating with their kinetochores. Each chromatid has a kinetochore, so a sister chromatid pair has two kinetochores, each of which becomes attached to opposite spindle poles during prometaphase in a critical process we discuss in detail below. When sister chromatids are attached to both spindle poles, they are said to be **bi-oriented**. They then become aligned equidistant between the two spindle poles in a process known as **congression**. Prometaphase continues until all chromosomes have congressed, at which point the cell enters the next stage, **metaphase**, defined as the stage when all the chromosomes are aligned at the **metaphase plate**.

The next stage, **anaphase**, is induced by activation of the anaphase-promoting complex/cyclosome (APC/C) (discussed in Chapter 19). The activated APC/C (through several intermediary steps) ultimately leads to the destruction of the cohesins

Contractile ring forms cleavage furrow

that were holding the sister chromatids together, so that now each separated chromosome can be pulled to its respective pole by the microtubules attached to its kinetochore. This movement is known as *anaphase A*. A separate and distinct movement also occurs: the movement of the spindle poles farther apart in a process known as *anaphase B*. Now that the chromosomes have separated, the cell enters *telophase*, when the nuclear envelope reforms, the chromosomes decondense, and the cell is pinched into two daughter cells by the contractile ring during *cytokinesis*.

The Mitotic Spindle Contains Three Classes of Microtubules

Before we discuss the mechanisms involved in the remarkable process of mitosis, it is important to understand the three distinct classes of microtubules that emanate from the spindle poles, which is where all their (–) ends are embedded. The first class is the *astral microtubules*, which extend from the spindle poles to the cell cortex (Figure 18-37). By interacting with the cortex, the astral microtubules perform the critical function of orienting the spindle with the axis of cell division. The second class, *kinetochore microtubules*, function by a search-and-capture mechanism to link the spindle poles to the kinetochores on sister chromatid pairs. During anaphase A, the kinetochore microtubules transport the newly separated chromosomes to their respective poles. The third set of microtubules extend from each spindle pole body

toward the opposite one and interact together in an antiparallel manner; these are called *polar microtubules*. These microtubules are responsible initially for pushing the duplicated centrosomes apart during prophase, then for maintaining the structure of the spindle, and then for pushing the spindle poles apart in anaphase B.

Note that all the microtubules in each half of the symmetrical spindle have the same orientation except for some polar microtubules, which extend beyond the midpoint and interdigitate with polar microtubules from the opposite pole.

Microtubule Dynamics Increase Dramatically in Mitosis

Although we have drawn static images of the stages of mitosis, microtubules in all stages of mitosis are highly dynamic. As discussed previously, as cells enter mitosis, the ability of their centrosomes to nucleate assembly of microtubules increases significantly (see Figure 18-35). In addition, microtubules become much more dynamic. How was this determined? In principle, you could watch microtubules and follow their individual behaviors. However, in general, there are too many microtubules in a mitotic spindle to do this. To get an average value for how dynamic microtubules are, researchers have introduced fluorescent labeled tubulin into cells, which becomes incorporated randomly into all microtubules. They then bleach the fluorescent label in a small region of the mitotic spindle and measure the rate at which fluorescence

FIGURE 18-37 Mitotic spindles have three distinct classes of microtubules. (a) In this high-voltage electron micrograph, microtubules were stained with biotin-tagged anti-tubulin antibodies to increase their size. The large cylindrical objects are chromosomes. (b) Schematic diagram corresponding to the metaphase cell in (a). Three sets of microtubules (MTs) make up the mitotic apparatus. All the

microtubules have their (-) ends at the poles. Astral microtubules project toward the cortex and are linked to it. Kinetochore microtubules are connected to chromosomes. Polar microtubules project toward the cell center with their distal (+) ends overlapping. The spindle pole and associated microtubules is also known as a mitotic aster. [Part (a) courtesy of J. R. McIntosh.]

comes back in a technique known as *fluorescence recovery after photobleaching (FRAP)* (see Figure 9-21). Since the recovery of fluorescence is due to assembly of new microtubules from soluble fluorescent tubulin dimers, this represents the average rate at which microtubules turn over. In a mitotic spindle, their half-life is about 15 seconds, whereas in an interphase cell, it is about 5 minutes. It should be noted that these are bulk measurements and individual microtubules can be more stable or dynamic, as we will see.

What makes microtubules more dynamic in mitosis? As we discussed earlier, dynamic instability is a measure of relative contributions of growth rates, shrinkage rates, catastrophes, and rescues (see Figure 18-9). Analysis of microtubule dynamics *in vivo* shows that the enhanced dynamics of individual microtubules in mitosis is mostly generated by increased catastrophes and fewer rescues, with little change in rates of growth (i.e., lengthening) or shrinkage (i.e., shortening). Studies with extracts from frog oocytes have suggested that the main factor enhancing catastrophes in both interphase and mitotic extracts is depolymerization by kinesin-13 proteins. This can be seen in an *in vitro* assay where microtubule assembly from pure tubulin is nucleated from purified centrosomes (Figure 18-38a). If kinesin-13 is added into the assay, many fewer microtubules are formed. However, if the stabilizing microtubule-associated protein called XMAP215 is added with the kinesin-13, many microtubules are formed due to a dramatic reduction in catastrophe frequency. It turns out that the activity of kinesin-13 does not change significantly during the cell cycle, whereas the activity of XMAP215

is inhibited by its phosphorylation during mitosis (Figure 18-38b). This results in much more unstable (more dynamic) microtubules as the cell enters mitosis (Figure 18-38c).

Mitotic Asters Are Pushed Apart by Kinesin-5 and Oriented by Dynein

As the two mitotic asters form, they generate interdigitated microtubules of opposite polarity between them. During prophase, the bipolar kinesin-5 interacts with the antiparallel microtubules and, by moving toward the (+) end of each microtubule, slides them apart and thereby pushes the two asters apart. The (-) end-directed motor, cytoplasmic dynein, can also contribute to aster separation as well as orienting the spindle appropriately in the cell. Dynein does this by associating with the plasma membrane and pulling on microtubules nucleated from the mitotic asters. As we discuss shortly, this same mechanism is used to elongate the spindle during anaphase B (see Figure 18-42).

Chromosomes Are Captured and Oriented During Prometaphase

Kinetochores, the structures that mediate attachment between chromosomes and microtubules, assemble on each sister chromatid at a region called the **centromere**. The centromere is a constricted region of the condensed chromosome defined by a centromeric DNA sequence. Centromeric DNA can vary enormously in size; in budding yeast it is

EXPERIMENTAL FIGURE 18-38
Microtubule dynamics increase in mitosis due to loss of a stabilizing MAP. (a) These three panels reveal the ability of centrosomes to assemble microtubules from pure tubulin (left); tubulin and the destabilizing protein kinesin-13 (middle); or tubulin, kinesin-13, and the stabilizing protein XMAP215 (*Xenopus* MAP of 215kD) (right). Further analysis shows that the major effect of XMAP215 is to suppress catastrophes induced by kinesin-13. (b) The increased dynamics of microtubules in mitosis is due to the inactivation of XMAP215 by phosphorylation. (c) Diagram relating the different stabilities of microtubules in interphase and mitosis. Note that in addition to differential stability between interphase and mitosis, the ability of MTOCs to nucleate microtubules also increases dramatically in mitosis. [Part (a) from Kinoshita et al., 2001, *Science* 294:1340–1343. Part (b) from Kinoshita et al., 2002, *Trends Cell Biol.* 12:267–273.]

about 125 base pairs, whereas in humans it is on the order of 1 Mbp (see Chapter 6). Kinetochores contain many protein complexes to facilitate the linkage between centromeric DNA and microtubules. In animal cells, the kinetochore consists of a centromeric DNA layer and inner and outer

kinetochore layers, with the (+) ends of the kinetochore microtubules terminating in the outer layer (Figure 18-39). Yeast kinetochores are attached by a single microtubule to their spindle pole, human kinetochores are attached by about 30, and plant chromosomes by hundreds.

FIGURE 18-39 The structure of a mammalian kinetochore. Diagram and electron micrograph of a mammalian kinetochore.

[Modified from B. McEwen et al., 1998, *Chromosoma* 107:366; courtesy of B. McEwen.]

How does a kinetochore become attached to microtubules in prometaphase? Microtubules nucleated from the spindle poles are very dynamic, and when they contact the kinetochore, either laterally or at their end, this can lead to chromosomal attachment (Figure 18-40a, steps 1a and 1b). Microtubules “captured” by kinetochores are selectively sta-

bilized by reducing the level of catastrophes, thereby promoting the chance that the attachment will persist.

Recent studies have uncovered a mechanism involving Ran, a small GTPase, that enhances the chance that microtubules will encounter kinetochores. Recall that during interphase the Ran GTPase cycle is involved in transport of

VIDEO: Microtubule Dynamics in Mitosis
FOCUS ANIMATION: Microtubule Dynamics

FIGURE 18-40 Chromosome capture and congression in prometaphase. (a) In the first stage of prometaphase, chromosomes become attached, either to the end of a microtubule (1a) or to the side of a microtubule (1b). The chromosome is then drawn toward the spindle pole by dynein-dynactin associated with one of the kinetochores of the chromosome, as this motor moves toward the (–) end of the microtubule (2). Eventually, a microtubule from the opposite pole finds and becomes attached to the free kinetochore, and the chromosome is now said to be bi-oriented (3). Once some chromosomes are bi-oriented, others, having established one kinetochore-pole interaction, use CENP-E/kinesin-7 on their free kinetochore to aid in orientation (4). The bi-oriented chromosomes then move to a central point between the spindle poles in a process known as chromosome congression. Note that during these steps, chromosome arms point

away from the closest spindle pole: this is due to chromokinesin/kinesin-4 motors on the chromosome arms moving toward the (+) ends of the polar microtubules. In animal cells, many microtubules associate with each kinetochore. For ease of presentation, only single kinetochore microtubules are shown. (b) Congression involves bidirectional oscillations of chromosomes, with one set of kinetochore microtubules shortening on one side of the chromosomes and the other set lengthening on the other. On the shortening side, a kinesin-13 protein stimulates microtubule disassembly and a dynein-dynactin complex moves the chromosome toward the pole. On the side with lengthening microtubules, kinesin-7 protein holds on to the growing microtubule. The kinetochore also contains many additional protein complexes not shown here. [Modified from Cleveland et al., 2003, *Cell* 112:407–421.]

proteins into and out of the nucleus through nuclear pores (Chapter 13; see Figure 13-37). During mitosis, when the nuclear membrane and pores have disassembled, an exchange factor for the Ran GTPase is bound to chromosomes, thereby generating a higher local concentration of Ran-GTP in the vicinity of the chromosomes. Because the enzyme that stimulates GTP hydrolysis on Ran—the Ran GAP—is evenly distributed in the cytosol, this generates a gradient of Ran-GTP centered on the chromosomes. Ran-GTP induces the association of cytosolic microtubule-stabilizing factors with the microtubule, resulting in enhanced microtubule growth, and in this way biases growth of microtubules nucleated from spindle poles toward chromosomes.

Once a kinetochore is attached laterally or terminally to a microtubule, the motor protein dynein-dynactin associates with the kinetochore to move the duplicated chromosome down the microtubule toward the spindle pole. This eventually results in an end-on attachment of the microtubule to one kinetochore (Figure 18-40a, step 2). This movement helps orient the sister chromatid so that the unoccupied kinetochore on the opposite side is pointing toward the distal spindle pole. Eventually a microtubule from the distal pole will capture the free kinetochore; at this point the sister chromatid pair is now said to be *bi-oriented* (Figure 18-40a, step 3). With the two kinetochores attached to opposite poles, the duplicated chromosome is now under tension, being pulled in both directions by the two sets of kinetochore microtubules. When one or a few chromosomes are bi-oriented, other chromosomes use these existing kinetochore microtubules to contribute to their orientation and movement to the spindle center. This is mediated by kinesin-7 (also known as CENP-E) associated with the free kinetochore moving the chromosome to the (+) end of the kinetochore microtubule (Figure 18-40a, step 4).

Duplicated Chromosomes Are Aligned by Motors and Microtubule Dynamics

During prometaphase, the chromosomes come to lie at the midpoint between the two spindle poles, in a process known as chromosome *congression*. During this process, bi-oriented chromosome pairs often oscillate backward and forward before arriving at the midpoint. Chromosome congression involves the coordinated activity of several microtubule-based motors together with regulators of microtubule assembly and disassembly (Figure 18-40b). These regulators are localized at the kinetochores, but how they are maintained there is poorly understood—they are not part of the stable kinetochore complexes described in the next section. The oscillating behavior of chromosomes involves lengthening of microtubules attached to one kinetochore and shortening of microtubules attached to the other kinetochore, all without losing their attachments. In metazoans, several microtubule-based motors associated with the kinetochore contribute to this process. First, dynein-dynactin provides the strongest force pulling the chromosome pair toward the more *distant* pole. This movement requires simultaneous shortening of the microtubule, which is enhanced by kinetochore-localized kinesin-13. The microtubules associ-

ated with the other kinetochore have to grow as the chromosome moves. Anchored at this kinetochore is the kinesin-related motor kinesin-7, which holds on to the growing (+) end of the lengthening microtubule. Also contributing to congression is another kinesin, kinesin-4, which associates with the chromosome arms. Kinesin-4, a (+) end-directed motor, interacts with the polar microtubules to pull the chromosomes toward the center of the spindle. When the chromosomes have congressed to the metaphase plate, dynein-dynactin is released from the kinetochores and streams down the kinetochore microtubules to the poles. These different activities and opposing forces work together to bring all the chromosomes to the metaphase plate, at which point the cell is ready for anaphase.

The Chromosomal Passenger Complex Regulates Microtubule Attachment at Kinetochores

We have mentioned that the segregation of chromosomes at mitosis must be very accurate, so it is crucial that all chromosomes are bi-oriented before anaphase begins. During the random kinetochore-to-microtubule attachment process, it is possible for mistakes to be made; for example, both kinetochores of a sister chromatid pair may attach to microtubules from the same spindle pole. If such attachments persisted during metaphase, it would result in one cell missing a chromosome and the other having an extra one, both lethal conditions. Cells have two important mechanisms to ensure that all chromosomes are correctly bi-oriented before anaphase begins.

The first mechanism ensures that the kinetochore-microtubule interactions are weak until bi-orientation occurs. When a chromosome is correctly bi-oriented, tension is produced across the chromosome and this tension leads to the kinetochore-microtubule attachments becoming stabilized. To understand how this works, we need to look a bit closer at the molecular components that link a kinetochore to a microtubule. As we discussed in Chapter 6, kinetochores assemble on regions of chromosomal DNA marked by a specific centromeric-specific H3 histone variant called CENP-A. This marks the site for kinetochore assembly, which is a very complicated process. About half a dozen distinct stable protein complexes consisting of more than 40 different proteins have been shown to associate with this centromeric region in yeast. Essentially all these protein complexes are conserved in humans, which is not surprising because of the fundamental importance of kinetochores. One of these, the so-called Ndc80 complex, is long and flexible, and many copies of it link the inner kinetochore with the (+) end of the microtubule in a sleeve type of arrangement (Figure 18-41a). The function of Ndc80 and many of the associated factors at the kinetochore is regulated by the *chromosomal passenger complex* (CPC). This complex associates with the inner centromeric region of chromosomes early in mitosis, and among its components is a protein kinase called *Aurora B*. Recent work has shown that part of the initial mechanism for recruitment of the CPC is through its binding to phosphorylated CENP-A. Once associated with the centromeric region, Aurora B within the CPC can phosphorylate several components in the near vicinity, including the

FIGURE 18-41 CPC regulation of microtubule-kinetochore attachment.

The Ndc80 complex forms a critical and regulated attachment between the kinetochore and microtubule (+) ends, (a) Diagram showing the sleeve arrangement of Ndc80 complex linking the inner plate of the kinetochore to the (+) end of a microtubule embedded in the outer plate. (b) Diagram of the relationship between the chromosomal passenger complex (CPC), which contains the kinase Aurora B, and the outer kinetochore where the phosphatase PP1 binds. Notice that when both kinetochores are under tension the outer kinetochores move away from the CPC; as a result, Aurora B cannot phosphorylate components in the outer plate, which includes the microtubule-binding site of the Ndc80 complex. (c) Cell in the metaphase stage of mitosis stained for tubulin (red), DNA (blue), Aurora B kinase (green), and centromeres (magenta). Notice how the centromeres are pulled away from Aurora B (inset). [(a) Modified from S. Santaguida and A. Musacchio, 2009, *EMBO J.* 28:2511–2531.

(c) From S. Ruchaud, M. Carmena, and W. C. Earnshaw, 2007, *Nature Rev. Mol. Cell Biol.* 8:798–812.]

Ndc80 complex, which loosens the attachment of Ndc80 to the microtubule. The phosphorylation of these components is not stable—another protein, the phosphatase PP1 associated with the outer kinetochore, can dephosphorylate them. Thus when the kinetochores on a pair of sister chromatids are not under tension, Ndc80 is continually phosphorylated by CPC and dephosphorylated by PP1. The result is a weak interaction between the kinetochore and microtubule. However, when bi-orientation occurs, the tension generated pulls on both kinetochores to move them away from the CPC (Figure 18-41b, c). Additionally, it is believed that the tension extends the flexible Ndc80 complex to increase the spacing between the inner and outer kinetochore plates. As a result of these movements, Ndc80 cannot be phosphorylated by Aurora B and the dephosphorylated state of Ndc80 renders it more firmly attached to the microtubule. In this way, microtubule attachments to bi-oriented chromosomes are selectively stabilized. While the CPC is important for bi-orientation of each individual chromosome, this does not ensure that *all* chromosomes are bi-oriented before anaphase begins.

The second mechanism to ensure correct chromosome segregation is the spindle assembly checkpoint, a signaling

circuitry that stops progression of the cell cycle into anaphase until tension is present at *all* the kinetochores. This mechanism, discussed in detail in Chapter 19, guarantees that all the chromosomes are correctly bi-oriented before the cell proceeds into anaphase.

Anaphase A Moves Chromosomes to Poles by Microtubule Shortening

The onset of anaphase A is one of the most dramatic movements that can be observed in the light microscope. When the spindle assembly checkpoint has been satisfied, APC/C activation induces proteolysis of the remaining cohesins holding the sister chromatids together. Suddenly, the two paired sister chromatids separate from each other and are drawn to their respective poles. The movement is sudden because the kinetochore microtubules are under tension, and as soon as the cohesin attachments between the chromatids are released, the separated chromosomes are free to move.

Experiments with isolated metaphase chromosomes have shown that anaphase A movement can be powered by microtubule shortening, utilizing the stored structural strain

released by removing the GTP-bound tubulin subunits at the microtubule tip. This can be nicely demonstrated *in vitro*. When metaphase chromosomes are added to purified microtubules, they bind preferentially to the (+) ends of the microtubules. Dilution of the mixture to reduce the concentration of free tubulin dimers results in the movement of the chromosomes toward the (-) ends by microtubule depolymerization at the chromosome-bound (+) end. In addition, recent experiments have shown that in *Drosophila* two kinesin-13 proteins, members of a class of microtubule-depolymerizing proteins (see Figure 18-15), also contribute to chromosome movement in anaphase A. One of the kinesin-13 proteins is localized at the kinetochore and enhances disassembly there (Figure 18-42, **A1**), and the other is localized at the spindle pole, enhancing depolymerization there (Figure 18-42, **A2**). Thus, at least in the fly, anaphase A is powered in part by kinesin-13 proteins specifically localized at the kinetochore

and spindle pole to shorten the kinetochore microtubules at both their (+) and (-) ends, drawing the chromosomes to the poles.

Anaphase B Separates Poles by the Combined Action of Kinesins and Dynein

The second part of anaphase involves separation of the spindle poles in a process known as anaphase B. A major contributor to this movement is the involvement of the bipolar kinesin-5 proteins (Figure 18-42, **B1**). These motors associate with the overlapping polar microtubules, and since they are (+) end-directed motors, they push the poles apart. While this is happening, the polar microtubules have to grow to accommodate the increased distance between the spindle poles. Another motor—the microtubule (-) end-directed motor cytoplasmic dynein, localized and anchored on the

FIGURE 18-42 Chromosome movement and spindle pole separation in anaphase. Anaphase A movement is powered by microtubule-shortening kinesin-13 proteins at the kinetochore (**A1**) and at the spindle pole (**A2**). Note that the chromosome arms still point away from the spindle poles due to associated chromokinesin/kinesin-4 members, so the depolymerization force has to be able to

overcome the force pulling the arms toward the center of the spindle. Anaphase B also has two components: sliding of antiparallel polar microtubules powered by a kinesin-5 (+) end-directed motor (**B1**), and pulling on astral microtubules by dynein-dynactin located at the cell cortex (**B2**). Arrows indicate the direction of movement generated by the respective forces. [Modified from Cleveland et al., 2003, *Cell* 112:407–421.]

EXPERIMENTAL FIGURE 18-43 Mitotic spindles can form in the absence of centrosomes. Centrosome-free extracts can be isolated from frog oocytes arrested in mitosis by centrifuging eggs to separate a soluble material from the organelles and yolk. When fluorescently labeled tubulin (green) is added to extracts of the soluble

material together with beads covered with DNA (red), mitotic spindles spontaneously form around the beads from randomly nucleated microtubules. [Modified from Kinoshita et al, 2002, *Trends Cell Biol.* **12**:267–273, and Antonio et al., 2000, *Cell* **102**:425.]

cell cortex—pulls on the astral microtubules and thus helps separate the spindle poles (Figure 18-42, **B2**).

Additional Mechanisms Contribute to Spindle Formation

There are a number of cases *in vivo* where spindles form in the absence of centrosomes. This implies that nucleation of microtubules from centrosomes is not the only way a spindle can form. Studies exploiting mitotic extracts from frog eggs—extracts that do not contain centrosomes—show that the addition of beads covered with DNA is sufficient to assemble a relatively normal mitotic spindle (Figure 18-43). In this system, the beads recruit preformed microtubules, and factors in the extract cooperate to make a spindle. One of the factors necessary for this reaction is cytoplasmic dynein, which is proposed to bind to two microtubules and migrate to their (–) ends, thereby drawing them together.

As mentioned in Section 18.1, recent work has identified a new γ -TuRC-associated complex, the *augmin complex*, that also contributes microtubules to the mitotic spindle. In late prometaphase and metaphase, the augmin complex binds the sides of existing spindle microtubules to nucleate additional microtubules that contribute especially to polar microtubules, and therefore anaphase B movement. Polar microtubules are also involved in the placement of the contractile ring, as we discuss next.

Cytokinesis Splits the Duplicated Cell in Two

During late anaphase and telophase in animal cells, the cell assembles a microfilament-based *contractile ring* attached to the plasma membrane that will eventually contract and pinch the cell into two, a process known as cytokinesis (see Figure 18-36). The contractile ring is a thin band of actin filaments of mixed polarity interspersed with myosin-II bipolar filaments (see Figure 17-36). On receiving a signal, the ring contracts first to generate a *cleavage furrow* and then to pinch the cell into two.

Two aspects of the contractile ring are essential to its function. First, it has to be appropriately placed in the cell. It is known that this placement is determined by signals provided by the spindle, so that the ring forms equidistant between the two spindle poles. The signal is provided, at least in part, by the chromosomal passenger complex (CPC) that regulates the attachment of microtubules to kinetochores during prometaphase (see Figure 18-41). Up to anaphase, the CPC is associated with the centromeric region of unseparated chromosomes. When anaphase begins, it leaves the centromeres and associates with the overlapping polar microtubules at the center of the spindle (Figure 18-44). There the CPC recruits another protein complex, *centralspindlin*, that includes a (+) end-directed kinesin

Anaphase

Telophase

EXPERIMENTAL FIGURE 18-44 The Chromosomal Passenger Complex (CPC) remains at the spindle midzone during anaphase and telophase. Micrographs of a cell in late anaphase (left) and telophase (right) showing microtubules (red), DNA (blue), Aurora B kinase (green), and chromosome centromeres (magenta). Notice how the Aurora B in the CPC complex concentrates in the region where the polar microtubules overlap and where the contractile ring will form. Scale bar = 5 μ m. [From S. Ruchard, M. Carmena, and W. C. Earnshaw, 2007, *Nature Rev. Mol. Cell Biol.* **8**:798–812.]

motor protein, which concentrates at the middle of the spindle due to its motor activity. As anaphase B continues, centralspin-dlin recruits an exchange factor for RhoA. Recall from Chapter 17 that Rho proteins are small GTP-binding proteins that are activated by exchange factors to catalyze the exchange of GDP for GTP (see Figure 17-42). Once activated, the RhoA-GTP activates a formin protein to drive the nucleation and assembly of actin filaments that make up the contractile ring (see Figure 17-44). In this way, the position of the spindle directly defines the site of contractile ring formation, and hence cytokinesis.

The second important aspect of the contractile ring is the timing of its contraction—if it were to contract before all chromosomes have moved to their respective poles, disastrous genetic consequences would ensue. As we discuss in Chapter 19, a signaling pathway has been discovered in budding yeast called the *spindle position checkpoint* that pauses the cell cycle to ensure that cytokinesis does not occur until the spindle is appropriately oriented. The mechanism of this coordination in animal cells is still being unraveled.

Plant Cells Reorganize Their Microtubules and Build a New Cell Wall in Mitosis

Interphase plant cells lack a central MTOC that organizes microtubules into the radiating interphase array typical of animal cells. Instead, numerous MTOCs containing γ -tubulin line the cortex of plant cells and nucleate the assembly of transverse bands of microtubules below the cell wall (Figure 18-45, *left*). The microtubules, which are of mixed polarity, are released from the cortical MTOCs by the action of katanin, a microtubule-severing protein; loss of katanin gives rise to very long microtubules and misshapen cells. The reason for this is that these cortical microtubules, which are cross-linked by plant-specific MAPs, aid in laying down extracellular cellulose microfibrils, the main component of the rigid cell wall (see Figure 20-40).

Although mitotic events in plant cells are generally similar to those in animal cells, formation of the spindle and cytokinesis have unique features in plants (Figure 18-45). Plant cells

FIGURE 18-45 Mitosis in a higher plant cell. Immunofluorescence micrographs (*top*) and corresponding diagrams (*bottom*) showing arrangement of microtubules in interphase and mitotic plant cells. A cortical array of microtubules girdles a cell during interphase. As the cell enters prophase, the microtubules (green), together with actin filaments (red) assemble under the cell cortex into the preprophase band that marks the future division site. As the cell enters prometaphase and metaphase, a spindle forms similar to that seen in animal cells. However, due to the cell wall, cytokinesis is very different in plants

than in animal cells. Microtubules deliver membranes to assemble a nascent cell plate called a phragmoplast, whose organization is defined by actin filaments linked to the cortical division site. Eventually, the newly delivered membranes fuse at the cortical division site and become part of the plasma membranes of the two cells. Enzymes secreted with the vesicles then build a cell wall between the two daughter cells. [Adapted from G. Jurgens, 2005, *Ann. Rev. Plant Biol.* 56:281–289; micrographs courtesy of Susan M. Wick.]

bundle their cortical microtubules and actin filaments into a *preprophase band* and reorganize them into a spindle at prophase without the aid of centrosomes. The site of the preprophase band defines the later division site. At metaphase, the mitotic apparatus appears much the same in plant and animal cells. However, the division of the cell into two is quite different from animal cells. Golgi-derived vesicles, which appear at telophase, are transported along microtubules to form the *nascent cell plate*. The cell plate expands and is guided toward the division site by actin filaments to form the **phragmoplast**, a membrane structure that replaces the animal-cell contractile ring. The membranes of the vesicles forming the phragmoplast become the plasma membranes of the daughter cells. The contents of these vesicles, such as polysaccharide precursors of cellulose and pectin, form the early cell plate, which develops into the new cell wall between the daughter cells.

KEY CONCEPTS of Section 18.6

Mitosis

- Mitosis—the accurate separation of duplicated chromosomes—involves a molecular machine comprising dynamic microtubules and microtubule-associated motors.
- The mitotic spindle has three classes of microtubules, all emanating from the spindle poles—kinetochore microtubules, which attach to chromosomes; polar microtubules from each spindle pole, which overlap in the middle of the spindle; and astral microtubules, which extend to the cell cortex (see Figure 18-37).
- In the first stage of mitosis, prophase, the nuclear chromosomes condense and the spindle poles move to either side of the nucleus (see Figure 18-36).
- At prometaphase, the nuclear envelope breaks down and microtubules emanating from the spindle poles capture sister chromatid pairs at their kinetochores. The two kinetochores (one on each chromatid) become attached to opposite spindle poles (bi-oriented), which allows the chromosome to congress to the middle of the spindle.
- The chromosomal passenger complex (CPC) associated with the inner kinetochore plate keeps microtubule attachments weak by the activity of its kinase component Aurora B, which phosphorylates critical kinetochore proteins. When a chromosome is bi-oriented, tension is generated and the Aurora B substrates are pulled away from the kinase (see Figure 18-41). Without phosphorylation of kinetochore proteins by Aurora B, the chromosome-kinetochore attachment becomes stable.
- At metaphase, chromosomes are aligned on the metaphase plate. The spindle assembly checkpoint system monitors unattached kinetochores and delays anaphase until all chromosomes are attached.
- At anaphase, duplicated chromosomes separate and move toward the spindle poles by shortening of the kinetochore microtubules at both the kinetochore and spindle pole (anaphase A). The spindle poles also move apart, pushed by bipolar kinesin-5

moving toward the (+) ends of the polar microtubules (anaphase B). Spindle separation is also facilitated by cortically located dynein pulling on astral microtubules (see Figure 18-42).

- Since the mitotic spindle has the ability to self-assemble in the absence of MTOCs, redundant mechanisms apparently contribute to the fidelity of mitosis.
- The actin-myosin-based contractile ring, the position of which is determined by the position of the spindle, contracts to pinch the cell in two during cytokinesis.
- In plants, cell division involves the delivery of membranes by microtubules to assemble the phragmoplast, which becomes the plasma membrane of the two daughter cells.

18.7 Intermediate Filaments

The third major filament system of eukaryotes is collectively called **intermediate filaments**. This name reflects their diameter of about 10 nm, which is intermediate between the 6–8 nm of microfilaments and the myosin thick filaments of skeletal muscle. Intermediate filaments extend throughout the cytoplasm as well as lining the inner nuclear envelope of interphase animal cells (Figure 18-46). Intermediate filaments have several

EXPERIMENTAL FIGURE 18-46 Localization of two types of intermediate filaments in an epithelial cell. A meshwork of lamin intermediate filaments can be seen underlying the nuclear membrane, whereas the keratin filaments extend from the nucleus to the plasma membrane. [Courtesy of R. D. Goldman.]

unique properties that distinguish them from microfilaments and microtubules. First, they are biochemically much more heterogeneous—that is, many different, but evolutionarily related, intermediate filament subunits exist—and are often expressed in a tissue-dependent manner. Second, they have great tensile strength, as clearly demonstrated by hair and nails, which consist primarily of the intermediate filaments of dead cells. Third, they do not have an intrinsic polarity like microfilaments and microtubules, and their constituent subunits do not bind a nucleotide. Fourth, because they have no intrinsic polarity, it is not surprising that there are no known motors that use them as tracks. Fifth, although they are dynamic in terms of subunit exchange, they are much more stable than microfilaments and microtubules because the exchange rate is much slower. Indeed, a standard way to purify intermediate filaments is to subject cells to harsh extraction conditions in a detergent so that all membranes, microfilaments, and microtubules are solubilized, leaving a residue that is almost exclusively intermediate filaments. Finally, intermediate filaments are not found in all eukaryotes. Fungi and plants do not have intermediate filaments, and insects only have one class, represented by two genes that express lamin A/C and B.

These properties make intermediate filaments unique and important structures of metazoans. The importance of intermediate filaments is underscored by the identification of more than 40 clinical disorders, some of which are discussed here, associated with defects in genes encoding intermediate filament proteins. To understand their contributions to cell

and tissue structure, we first examine the structure of intermediate filament proteins and how they assemble into filaments. We then describe the different classes of intermediate filaments and the functions they perform.

Intermediate Filaments Are Assembled from Subunit Dimers

Intermediate filaments (IFs) are encoded in the human genome by 70 different genes in at least five subfamilies. The defining feature of IF proteins is the presence of a conserved α -helical rod domain of about 310 residues that has the sequence features of a coiled-coil motif (see Figure 3-9a). Flanking the rod domain are nonhelical N- and C-terminal domains of different sizes, characteristic of each IF class.

The primary building block of intermediate filaments is a dimer held together through the rod domains that associate as a coiled-coil (Figure 18-47a). These dimers then associate in an offset fashion to make tetramers, where the two dimers are in opposite orientations (Figure 18-47b). Tetramers are assembled end-to-end and interlocked into long *protofilaments*. Four protofilaments associate into a *protofibril*, and four protofibrils associate side to side to generate the 10-nm filament. Thus an intermediate filament has 16 protofilaments in it (Figure 18-47c). Because the tetramer is symmetric, intermediate filaments have no polarity. This description of the filament is based on its structure rather than its mechanism of assembly: at present it is not yet clear how intermediate

FIGURE 18-47 Structure and assembly of intermediate filaments. Electron micrographs and drawings of IF protein dimers, tetramers, and mature intermediate filaments from *Ascaris*, an intestinal parasitic worm. (a) IF proteins form parallel dimers through a highly conserved coiled-coil core domain. The globular heads and tails are quite variable in length and sequence between intermediate

filament classes. (b) A tetramer is formed by antiparallel, staggered side-by-side aggregation of two identical dimers. (c) Tetramers aggregate end to end and laterally into a protofibril. In a mature filament, consisting of four protofibrils, the globular domains form beaded clusters on the surface. [Adapted from N. Geisler et al., 1998, *J. Mol. Biol.* **282**:601; courtesy of Ueli Aepli.]

filaments are assembled *in vivo*. Unlike microfilaments and microtubules, there are no known intermediate filament nucleating, sequestering, capping, or filament-severing proteins.

Intermediate Filament Proteins Are Expressed in a Tissue-Specific Manner

Sequence analysis of IF proteins reveals that they fall into at least five distinct homology classes, with four classes showing a strong correspondence between the sequence class and the developmental origin of the cell type in which the IF protein is expressed (Table 18-1).

The **keratins** that make up classes I and II are found in epithelia; class III IF proteins are generally found in cells of mesodermal origin; and class IV IF proteins compose the **neurofilaments** found in neurons. The **lamins**, which make up class V, are found lining the nucleus of all animal tissues. We briefly summarize the five different homology classes and discuss their roles in specific tissues.

Keratins Keratins provide strength to epithelial cells. The first two homology classes are the so-called *acidic* and *basic keratins*. There are about 50 genes in the human genome encoding keratins, about evenly split between the acidic and basic classes. These keratin subunits assemble into an obligate dimer, so that each dimer consists of one basic chain and one acidic chain; these are then assembled into a filament as described in the previous section.

The keratins are by far the most diverse of the IF protein families, with keratin pairs showing different expression patterns between distinct epithelia and also showing differentiation-specific regulation. Among these are the so-called hard keratins that make up hair and nails. These keratins are rich in cysteine residues that become oxidized to form disulfide bridges, thereby strengthening them. This property is exploited by hair stylists: if you do not like the shape of your hair, the disulfide bonds in your hair keratin can be reduced, the hair reshaped, and the disulfide bonds reformed by oxidation—the result is “permanent” hair curling or hair straightening.

The so-called soft, or *cyto-keratins*, are found in epithelial cells. The epidermal-cell layers that make up the skin provide a good example of the function of keratins. The lowest layer of cells, the *basal layer*, which is in contact with the basal lamina, proliferates constantly, giving rise to cells called *keratinocytes*. After they leave the basal layer, the keratinocytes differentiate and express abundant cytokeratins. The cytokeratins associate with specialized attachment sites between cells, thereby providing sheets of cells that can withstand abrasion. The cells eventually die, leaving dead cells from which all cell organelles have disappeared. This dead cell layer provides an essential barrier to water evaporation, without which we could not survive. The life of a skin cell, from birth to its loss from the animal as a skin flake, is about one month.

In all epithelia, keratin filaments associate with desmosomes, which link adjacent cells together, and hemidesmosomes, which link cells to the extracellular matrix, thereby

TABLE 18-1 The Major Classes of Intermediate Filaments in Mammals

Class	Protein	Distribution	Proposed Function	
I	Acidic keratins	Epithelial cells	Tissue strength and integrity	
II	Basic keratins	Epithelial cells		
III	Desmin, GFAP, vimentin	Muscle, glial cells, mesenchymal cells	Sarcomere organization, integrity	 
IV	Neurofilaments (NFL, NFM, and NFH)	Neurons	Axon organization	
V	Lamins	Nucleus	Nuclear structure and organization	

giving cells and tissues their strength. These structures are described in more detail in Chapter 20.

In addition to simply providing structural support, there is increasing evidence that keratin filaments provide some organization to organelles and participate in signal-transduction pathways. For example, in response to tissue injury, rapid cell growth is induced. In epithelial cells it has been shown that the growth signal requires an interaction between a cell-growth-signaling molecule and a specific keratin.

Desmin The class III intermediate filament proteins include vimentin, found in mesenchymal cells; GFAP (glial fibrillary acidic protein), found in glial cells; and *desmin*, found in muscle cells. Desmin provides strength and organization to muscle cells (see cartoons in Table 18-1).

In smooth muscle, desmin filaments link cytoplasmic *dense bodies*, to which the contractile myofibrils are also attached, to the plasma membrane to ensure that cells resist overstretching. In skeletal muscle, a lattice composed of a band of desmin filaments surrounds the sarcomere. The desmin filaments encircle the Z disk and are cross-linked to the plasma membrane. Longitudinal desmin filaments cross to neighboring Z disks within the myofibril, and connections between desmin filaments around Z disks in adjacent myofibrils serve to cross-link myofibrils into bundles within a muscle cell. The lattice is also attached to the sarcomere through interactions with myosin thick filaments. Because the desmin filaments lie outside the sarcomere, they do not actively participate in generating contractile forces. Rather, desmin plays an essential structural role in maintaining muscle integrity. In transgenic mice lacking desmin, for example, this supporting architecture is disrupted and Z disks are misaligned. The location and morphology of mitochondria in these mice are also abnormal, suggesting that these intermediate filaments may also contribute to organization of organelles.

Neurofilaments Type IV intermediate filaments consist of the three related subunits—NF-L, NF-M, and NF-H (for NF light, medium, and heavy)—that make up the neurofilaments found in the axons of nerve cells (see Figure 18-2). The three subunits differ mainly in the size of their C-terminal domains, and all form obligate heterodimers. Experiments with transgenic mice reveal that neurofilaments are necessary to establish the correct diameter of axons, which determines the rate at which nerve impulses are propagated down them.

Lamins The most widespread intermediate filaments are the class V lamins, which provide strength and support to the inner surface of the nuclear membrane (see Figure 18-46). Lamins are the progenitor of all IF proteins, with the cytoplasmic IFs arising by gene duplication and mutation. The lamins provide a two-dimensional network lying between the nuclear envelope and the chromatin in the nucleus. In humans, three genes encode lamins: one encodes A-type and C-type lamin and two encode B-type lamin. The B-type lamin appears to be the primordial gene and is expressed in all cells, whereas A- and C-type lamins are developmentally regulated. B-lamins are

post-translationally isoprenylated, which helps them associate with the inner nuclear envelope membrane. In addition, they bind inner nuclear membrane proteins such as emerin and lamin-associated polypeptides (LAP2). Lamins bind multiple proteins and have been proposed to play roles in large-scale chromatin organization and the spacing of nuclear pores. As cells enter mitosis, lamins become hyperphosphorylated and disassemble; in telophase they reassemble with the reassembling nuclear membrane (discussed in Chapter 19).

Intermediate Filaments Are Dynamic

Although intermediate filaments are much more stable than microtubules and microfilaments, IF protein subunits have been shown to be in dynamic equilibrium with the existing IF cytoskeleton. In one experiment, a biotin-labeled type I keratin was injected into fibroblasts; within 2 hours, the labeled protein had been incorporated into the already existing keratin cytoskeleton (Figure 18-48). The results of this experiment and others demonstrate that IF subunits in a soluble pool are able to add themselves to preexisting filaments and that subunits are able to dissociate from intact filaments.

The relative stability of intermediate filaments presents special challenges in mitotic cells, which must reorganize all three cytoskeletal networks in the course of the cell cycle. In particular, breakdown of the nuclear envelope early in mitosis depends on the disassembly of the lamin filaments that form a meshwork supporting the membrane. As discussed in Chapter 19, the phosphorylation of nuclear lamins by a mitotic cyclin-dependent kinase that becomes active early in mitosis (prophase) induces the disassembly of intact filaments and prevents their reassembly. Later in mitosis (telophase), removal of these phosphates by specific phosphatases promotes lamin reassembly, which is critical to re-formation of a nuclear envelope around the daughter chromosomes. The opposing actions of kinases and phosphatases thus provide a rapid mechanism for controlling the assembly state of lamin intermediate filaments. Other intermediate filaments undergo similar disassembly and reassembly in the cell cycle.

Defects in Lamins and Keratins Cause Many Diseases

 There are about 50 known mutations in the human gene for type-A lamin that are known to cause diseases, collectively called laminopathies, many of which cause forms of Emery-Dreifuss muscular dystrophy (EDMD). Other mutations in the lamin-A gene cause dilated cardiomyopathy. It is not yet clear why these type-A lamin mutations cause EDMD, but perhaps in muscle tissues the fragile nuclei cannot stand the stress and strains of the tissue, so they are the first to show symptoms. Interestingly, other forms of EDMD have been traced to mutations in emerin, the lamin-binding membrane protein of the inner nuclear envelope. Yet other mutations in type-A lamin cause progeria—accelerated aging. The Hutchinson-Gilford progeria (“prematurely old”) syndrome is caused by a splicing error that results in a lamin A with a defective C-terminal domain.

EXPERIMENTAL FIGURE 18-48 Keratin intermediate filaments are dynamic, as soluble keratin is incorporated into filaments. Monomeric type I keratin was purified, chemically labeled with biotin, and microinjected into living epithelial cells. The cells were then fixed at different times after injection and stained with an antibody to biotin and with antibodies to keratin. (a) At 20 minutes after injection, the injected biotin-labeled keratin is concentrated in small foci scattered throughout the cytoplasm (*left*) and has not been integrated into the endogenous keratin cytoskeleton (*right*). (b) After 4 hours, the biotin-labeled keratin (*left*) and the keratin filaments (*right*) display identical patterns, indicating that the microinjected protein has become incorporated into the existing cytoskeleton. [From R. K. Miller, K. Vistrom, and R. D. Goldman, 1991, *J. Cell Biol.* **113**:843; courtesy of R. D. Goldman.]

The structural integrity of the skin is essential in order to withstand abrasion. In humans and mice, the K4 and K14 keratin isoforms form heterodimers that assemble into protofilaments. A mutant K14 with deletions in either the N- or the C-terminal domain can form heterodimers *in vitro* but does not assemble into protofilaments. The expression of such mutant keratin proteins in cells causes IF networks to break down into aggregates. Transgenic mice that express a mutant K14 protein in the basal stem cells of the epidermis display gross skin abnormalities, primarily blistering of the epidermis, that resemble the human skin disease *epidermolysis bullosa simplex* (EBS). Histological examination of the blistered area reveals a high incidence of dead basal cells. Death of these cells appears to be caused by mechanical trauma from rubbing of the skin during movement of the limbs. Without their normal bundles of keratin filaments, the mutant basal cells become fragile and easily damaged, causing the overlying epidermal layers to delaminate and blister (Figure 18-49). Like the role of desmin filaments in supporting muscle tissue,

EXPERIMENTAL FIGURE 18-49 Transgenic mice carrying a mutant keratin gene exhibit blistering similar to that in the human disease epidermolysis bullosa simplex. Histological sections through the skin of a normal mouse and a transgenic mouse carrying a mutant K14 keratin gene are shown. In the normal mouse, the skin consists of a hard outer epidermal layer covering and in contact with the soft inner dermal layer. In the skin from the transgenic mouse, the two layers are separated (arrow) due to weakening of the cells at the base of the epidermis. [From P. Coulombe et al., 1991, *Cell* **66**:1301; courtesy of E. Fuchs.]

the general role of keratin filaments appears to be to maintain the structural integrity of epithelial tissues by mechanically reinforcing the connections between cells. ■

KEY CONCEPTS of Section 18.7

Intermediate Filaments

- Intermediate filaments are the only nonpolarized fibrous component of the cytoskeleton and do not have associated motor proteins. Intermediate filaments are built from coiled-coil dimers that associate in an antiparallel fashion into tetramers and then into protofilaments, 16 of which make up the filament (see Figure 18-47).
- There are five major classes of intermediate filament proteins, with the nuclear lamins (class V) being the most ancient and ubiquitous in animal cells. The other four classes show tissue-specific expression (see Table 18-1).
- Keratins (classes I and II) are found in animal hair and nails, as well as in cytokeratin filaments that associate with desmosomes in epithelial cells to provide the cells and tissue with strength.
- The class III filaments include vimentin, GFAP, and desmin, which provide structure and order to muscle Z disks and restrain smooth muscle from overextension.
- The neurofilaments make up class IV and are important for the structure of axons.
- Many diseases are associated with defects in intermediate filaments, especially laminopathies, which include a variety of conditions, and mutations in keratin genes, which can cause severe defects in skin (see Figure 18-49).

18.8 Coordination and Cooperation Between Cytoskeletal Elements

So far, we have generally discussed the three cytoskeletal filament classes—microfilaments, microtubules, and intermediate filaments—as though they function independently of one another. However, the fact that the microtubule-based mitotic spindle determines the site of formation of the microfilament-based contractile ring is just one example of how these two cytoskeletal systems are coordinated. Here we mention some other examples of linkages, physical and regulatory, between cytoskeletal elements and their integration into other aspects of cellular organization.

Intermediate Filament–Associated Proteins Contribute to Cellular Organization

A group of proteins collectively called *intermediate filament-associated proteins (IFAPs)* have been identified that co-purify with intermediate filaments. Among these are the family of

EXPERIMENTAL FIGURE 18-50 Gold-labeled antibody identifies plectin cross-links between intermediate filaments and microtubules. In this immunoelectron micrograph of a fibroblast cell, microtubules are highlighted in red, intermediate filaments in blue, and the short connecting fibers between them in green. Staining with gold-labeled antibodies to plectin (yellow) reveals that these connecting fibers contain plectin. [From T. M. Svitkina, A. B. Verkhovsky, and G. G. Borisy, 1996, *J. Cell Biol.* **135**:991; courtesy of T. M. Svitkina.]

plakins, which are involved in attaching intermediate filaments to other structures. Some of these associate with keratin filaments to link them to desmosomes, which are junctions between epithelial cells that provide stability to a tissue, and hemidesmosomes, which are located at regions of the plasma membrane where intermediate filaments are linked to the extracellular matrix (these topics are covered in detail in Chapter 20). Other plakins are found along intermediate filaments and have binding sites for microfilaments and microtubules. One of these proteins, called plectin, can be seen by immunoelectron microscopy to provide connections between microtubules and intermediate filaments (Figure 18-50).

Microfilaments and Microtubules Cooperate to Transport Melanosomes

Studies of mutant mice with light-colored coats have uncovered a pathway in which microtubules and microfilaments cooperate to transport pigment granules. The color pigment in the hair is produced in cells called melanocytes, cells very similar to the fish and frog melanophores discussed earlier (see Figure 18-28). Melanocytes are found in the hair follicle at the base of the hair shaft and contain pigment-laden granules called melanosomes. Melanosomes are transported to the dendritic extensions of melanocytes for subsequent exocytosis to the surrounding epithelial cells. Transport to the cell periphery is mediated, just as in frog melanophores, by a kinesin family member. At the periphery, they are then handed off to myosin V and delivered for exocytosis. If the myosin V system is defective, the melanosomes are not captured and stay in the cell body. Thus microtubules are responsible for the long-range transport of melanosomes, whereas microfilament-based

myosin V is responsible for capture and delivery at the cell cortex. This type of division of labor—long-range transport by microtubules and short range by microfilaments—has been found in many different systems, from transport in filamentous fungi to transport along axons.

Cdc42 Coordinates Microtubules and Microfilaments During Cell Migration

In Chapter 17, we discussed how the polarity of a migrating cell is regulated by Cdc42, which results in the formation of an actin-based leading edge at the front of the cell and contraction at the back (see Figure 17-46 and Figure 18-51, step 1). It turns out that Cdc42 activation at the cell front also leads to polarization of the microtubule cytoskeleton. This was originally studied in wound-healing assays (see Figure 17-45), where it was noticed that when the cells at the edge of a scratch are induced to polarize and move to fill in the empty space, the Golgi complex is moved to the front of the nucleus toward the cell front. Golgi localization at the front of the cell indicates that the centrosome moves to lie in front of the nucleus (recall that Golgi localization is dependent on the location of the MTOC; see Figures 18-1c, 18-27). Recent studies have suggested how this happens. Cdc42 activation at the front of the cell binds the polarity factor Par6, which results in the recruitment of the dynein-dynactin complex (Figure 18-51, step 2). Cortically localized dynein-dynactin then interacts with microtubules, pulling on them to orient the centrosome and hence the whole radial array of microtubules (Figure 18-51, step 3). This reorientation of the microtubule system leads to the reorganization of the secretory pathway to deliver secretory products, especially integrins to bind the extracellular matrix, to the front of the cell for attachment to the substratum for cell migration (Figure 18-51, step 4).

Advancement of Neural Growth Cones Is Coordinated by Microfilaments and Microtubules

The nervous system depends on the integration and transmission of signals by neurons. Neurons have specialized structures called dendrites that receive signals, and a single axon that terminates in one or more synapses on a target cell or cells (for example, another neuron or a muscle cell) (see Figure 18-2). It is critical that neurons make the right connections, so how are axons guided to their correct destinations? As the axon extends, it has a terminal growth cone that senses signals from the extracellular matrix and other cells to guide it along the right path. Therefore, how the growth cone receives and interprets cues to direct axon growth is critical to the function of the nervous system. Growth cones are very rich in actin, and typically have a broad lamellipodium and multiple filopodia (Figure 18-52a). Also essential for the guidance of growth cones are microtubules. Recall that axons have microtubules of uniform polarity on which materials for growth of the growth cone are transported by axonal transport (see Figure 18-5e). These microtubules extend into the growth cone and, together with actin, are involved in guiding the direction of advancement of the growth cone. While actin is necessary for the advancement of the growth cone, the microtubules and actin together are necessary to steer growth in the correct direction. Although the mechanisms have not been fully elucidated, it has been found that a local growth signal alters local actin dynamics with the result that microtubules extend into that region. It has also been found that microtubules in the shaft of the axon have post-translational modifications, such as acetylation, that stabilizes them, whereas the more dynamic microtubules in the growth cone often do not (Figure 18-52b).

FIGURE 18-51 Independent Cdc42 regulation of microfilaments and microtubules to polarize a migrating cell. Active Cdc42-GTP at the front of the cell leads to Rac and WASP activation, which results in the assembly of a microfilament-based leading edge (step 1). Independently, Cdc42-GTP also leads to the capture of microtubule (+) ends and the

activation of dynein (step 2). Together these pull on microtubules to orient the centrosome (step 3) toward the front of the cell. This reorientation polarizes the secretory pathway for the delivery along microtubules of adhesion molecules carried in secretory vesicles (step 4). [Based on studies in S. Etienne-Manneville et al., 2005, *J. Cell Biol.* 170:895–901.]

EXPERIMENTAL FIGURE 18-52 The neuronal growth cone contains dynamic actin filaments and microtubules. (a) Two growth cones viewed by DIC microscopy showing their regions of filopodia and lamellipodia. (b) Localization of actin (red), microtubules (green), and acetylated microtubules (blue) in a small growth cone. Notice how the stable acetylated microtubules are localized to the shaft of the axon and do not penetrate into the dynamic growth cone. [From E. W. Bent and F. B. Gertler, 2003, *Neuron* **40**:209–227].

KEY CONCEPTS of Section 18.8

Coordination and Cooperation Between Cytoskeletal Elements

- Intermediate filaments are linked both to specific attachment sites on the plasma membrane (called desmosomes and hemidesmosomes), and to microfilaments and microtubules (see Figure 18-50).
- In animal cells, microtubules are generally utilized for the long-range delivery of organelles, whereas microfilaments handle their local delivery.
- The signaling molecule Cdc42 coordinately regulates microfilaments and microtubules during cell migration.
- The advancement of growth cones in neurons requires the interplay of microfilaments and microtubules.

Perspectives for the Future

In Chapters 17 and 18 we have seen how microfilaments, microtubules, and intermediate filaments provide structure and organization to cells. Without this elaborate system, cells would lack all order and hence all possibility of function or division. The name “cytoskeleton” suggests a relatively static structure on which the cell organization is hung. However, the cytoskeleton is actually a dynamic framework

responding to signal-transduction pathways and operating both locally and globally to provide cells with order to undertake their functions.

In outline, we have elucidated many of the distinct and common functions of the three filament systems. We know most of the components and probably all the motors. However, in many ways this is just an exciting beginning. With the available sequenced genomes and, at least in principle, a complete inventory of the cytoskeletal components, we have a parts list. However, a parts list is just that; what we need is to understand how the parts come together in specific processes.

A very active area of research today is to use the parts list to systematically identify the localization (through GFP fusions), functions (through RNAi knockdown), and associated partners (through isolation of protein complexes) of all cytoskeletal components. Consider that there are about 45 genes in animals that encode members of the kinesin family, yet we only know what a small subset of them do or what cargo they carry and for what purpose. In each case it is reasonable to assume the motors are regulated, but very little is currently known about how. It will be important to understand how motors pick up the right cargo, and then dissociate from them when they arrive at their destination. As we begin to put all the pieces in place, it will be increasingly possible to reconstitute specific processes in vitro. Some aspects of the mitotic spindle have already been reconstituted, which is an encouraging beginning, but it will be some time before it is possible to reconstitute the whole process.

Structural biology is going to play a major role because it will allow us to see in detail how different components work. Consider the large number of proteins that associate with the microtubule (+) end, the so-called +TIPs. We know a bit about how they maintain their association at the tip, and recent work has suggested that associations can change in different parts of the cell—again, we are only just beginning to see how these processes are regulated.

Perhaps the biggest—and most exciting—challenge is to uncover how signal-transduction pathways coordinate functions between all the different cytoskeletal elements within single cells, and in different cellular contexts. How cells organize and regulate different processes in various regions within a single cell is only now beginning to be tackled. We are beginning to see glimpses of what is in store from the signal-transduction pathways that regulate cell polarity and allow cell migration.

Although all these studies are likely to be aimed at basic cell biology, as we can see from the studies of intraflagellar transport and intermediate filaments, such studies often open a window into the underlying basis of disease, from which strategies for treatments can be developed. The interplay between basic cell biology and medicine contributes immensely to the excitement and social value of working in this area.

Key Terms

anaphase 850	intraflagellar transport (IFT) 846
anterograde 833	keratins 862
asters 849	kinesins 833
axonal transport 833	kinetochores 850
axoneme 845	lamins 862
basal body 845	metaphase 850
centromere 852	microtubule 821
centrosome 824	microtubule-associated proteins (MAPs) 822
cilia 844	microtubule-organizing center (MTOC) 824
cytokinesis 851	mitosis 849
desmin 863	mitotic spindle 849
dynamic instability 828	neurofilaments 862
dyneins 833	primary cilium 847
flagella 844	prophase 849
γ -tubulin ring complex (γ -TuRC) 825	protofilament 822
intermediate filament 821	retrograde 833
intermediate filament-associated proteins (IFAPs) 865	telophase 851
	tubulin 822

Review the Concepts

1. Microtubules are polar filaments; that is, one end is different from the other. What is the basis for this polarity, how is polarity related to microtubule organization within the

cell, and how is polarity related to the intracellular movements powered by microtubule-dependent motors?

2. Microtubules both in vitro and in vivo undergo dynamic instability, and this type of assembly is thought to be intrinsic to the microtubule. What is the current model that accounts for dynamic instability?

3. In cells, microtubule assembly depends on other proteins as well as tubulin concentration and temperature. What types of proteins influence microtubule assembly in vivo, and how does each type affect assembly?

4. Microtubules within a cell appear to be arranged in specific arrays. What cellular structure is responsible for determining the arrangement of microtubules within a cell? How many of these structures are found in a typical cell? Describe how such structures serve to nucleate microtubule assembly.

5. Many drugs that inhibit mitosis bind specifically to tubulin, microtubules, or both. What diseases are such drugs used to treat? Functionally speaking, these drugs can be divided into two groups based on their effect on microtubule assembly. What are the two mechanisms by which such drugs alter microtubule structure?

6. Kinesin-1 was the first member of the kinesin motor family to be identified and therefore is perhaps the best-characterized family member. What fundamental property of kinesin was used to purify it?

7. Certain cellular components appear to move bidirectionally on microtubules. Describe how this is possible given that microtubule orientation is fixed by the MTOC.

8. The motile properties of kinesin motor proteins involve both the motor domain and the linker domain. Describe the role of each domain in kinesin movement, direction of movement, or both. Could kinesin-1 with one inactive head efficiently move a vesicle along a microtubule?

9. What features of the dynactin complex enable cytoplasmic dynein to transport cargo toward the microtubule (–) end? What effect could inhibition of dynactin interactions with the +TIP EB-1 have on spindle orientation in cells?

10. Cell swimming depends on appendages containing microtubules. What is the underlying structure of these appendages, and how do these structures generate the force required to produce swimming?

11. What effect would dynein inactivation have on kinesin-2-dependent IFT transport?

12. The mitotic spindle is often described as a microtubule-based cellular machine. The microtubules that constitute the mitotic spindle can be classified into three distinct types. What are the three types of spindle microtubules, and what is the function of each?

13. Mitotic spindle function relies heavily on microtubule motors. For each of the following motor proteins, predict the effect on spindle formation, function, or both of adding a drug that specifically inhibits only that motor: kinesin-5, kinesin-13, and kinesin-4.

14. The poleward movement of kinetochores, and hence chromatids, during anaphase A requires that kinetochores

maintain a hold on the shortening microtubules. How does a kinetochore hold on to shortening microtubules?

15. Anaphase B involves the separation of spindle poles. What forces have been proposed to drive this separation? What underlying molecular mechanisms are thought to provide these forces?

16. Cytokinesis, the process of cytoplasmic division, occurs shortly after the separated sister chromatids have neared the opposite spindle poles. How is the plane of cytokinesis determined? What are the respective roles of microtubules and actin filaments in cytokinesis?

17. The best strategy for treating a specific type of human tumor can depend on identifying the type of cell that became cancerous to give rise to the tumor. For some tumors that have metastasized (moved) to colonize a distant location, identifying the parental cell type can be difficult. Because the type of IF protein expressed is cell-type specific, using monoclonal antibodies that react with only one type of IF protein can help in this identification. Monoclonal antibodies against what IF proteins would you use to identify a) a sarcoma of muscle cell origin, b) an epithelial cell carcinoma, and c) an astrocytoma?

18. Explain why there are no known motors that use intermediate filaments as tracks.

19. Growth cones are highly mobile regions of developing neurons. What prevents the growth cone from moving or collapsing back into the main cell body like often occurs with lamellipodia?

Analyze the Data

1a. Kinesin-1 contains two identical heavy chains and therefore has two identical motor domains. In contrast, kinesin-5 contains four identical heavy chains. Electron microscopic analysis of metal-shadowed kinesins results in the images shown in the top panel. Pretreatment of these kinesins with an antibody that binds specifically to the kinesin motor domain results in the images shown in the lower panel. All four images are at the same approximate magnification. What can you deduce about the structure of kinesin-5 from these data?

b. To determine if kinesin-5 is a (+) or (−) end microtubule motor, polarity-marked microtubules are generated by assembling short microtubules from brightly fluorescent tubulin and then elongating those short, bright microtubules using less fluorescent tubulin. As a result, the microtubules are very fluorescent at one end and less fluorescent along most of their length. A perfusion chamber is then coated with purified kinesin-5, which becomes immobilized on the glass surface. The chamber is then perfused with the polarity-labeled microtubules and ATP, and microtubule gliding with respect to the immobilized kinesin-5 is observed. The following sequence of images is obtained. Which end of these microtubules, the bright or the less-bright end, is the (+) end? Do these microtubules glide on kinesin-5 with their (+) or (−) end leading? Based on these data, is kinesin-5 a (+) or (−) end microtubule motor?

c. Kinesin-5 can cross-bridge adjacent microtubules. Polarity-marked microtubules are assembled in which tubulin attached to a red fluorescent dye is assembled to form short red microtubules, which are then elongated with tubulin attached to a green fluorescent dye. The microtubules are mixed with kinesin-5 and observed by fluorescence microscopy as ATP is added. The following images show a time sequence of two overlapping and cross-bridged microtubules as ATP is added. The arrowhead is in a fixed position. Can you explain what happens when ATP is added to microtubules cross-bridged by kinesin-5?

d. Eg5 is a kinesin-5 family member in *Xenopus*. To understand Eg5 function in vivo, cells are transfected with RNAi

directed against this motor. The following images are obtained of mitotic cells. What function might Eg5 play in cells?

2. The PI3K/AKT signaling pathway is aberrant in a wide variety of cancers. In soft-tissue sarcoma (STS) cells, AKT1 activation induces cell motility and invasiveness, which leads to aggressive metastasis of the cells. AKT1 was shown to bind to vimentin (see Q-S Zhu et al., 2010, Vimentin is a novel AKT1 target mediating motility and invasion. *Onco-gene* 30:457–470; doi:10.1038/onc.2010.421; published on-line 20 September 2010).

a. To map the vimentin and AKT interaction domains, the vimentin and AKT1 full-length and fragment constructs indicated below were expressed as GST-fusion proteins. Each of the GST-fusion constructs bound to glutathione beads was used to pull down associated proteins from crude STS cell lysates. What did the Western blot analysis of the pellet using an AKT1 antibody reveal about the AKT-binding domain in vimentin? What did analysis of the pellet using a vimentin antibody reveal about the vimentin-binding domain in AKT1?

b. AKT1 is a kinase and therefore likely to phosphorylate vimentin. Sequence analysis revealed that serines (S) at positions 39 and 325 in vimentin were likely sites for AKT1

phosphorylation. To test whether one or both of these sites is phosphorylated by AKT1, each site was mutated to alanine (A), which cannot be phosphorylated. Each alanine-mutated vimentin was mixed with AKT1 and tested for phosphorylation by Western blot analysis using an antibody that reacts with AKT1-phosphorylated serines (PAS antibody). Which site(s) does AKT1 phosphorylate?

c. The propensity of cancer cells to metastasize can be measured with an invasion assay in which cells migrate through a filter coated with extracellular matrix (ECM) proteins. The more cells migrating through the ECM, the higher the propensity for metastasis. The invasion assay was used to monitor effects of expression of a permanently active AKT1 (AKT1DD) mutation and overexpression of wild-type vimentin, a vimentin mutation that cannot be phosphorylated by AKT1 (VIMS39A), and a phosphomimetic vimentin mutation (VIMS39D) in which mutation of S39 to an aspartate residue (D) mimics phosphorylation of the serine. What effect does vimentin overexpression and phosphorylation have on cell migration?

A two-cell *C. elegans* embryo stained with antibodies against tubulin (red) and CeBUB-1, a spindle checkpoint protein (green). DNA is stained with DAPI (blue). CeBUB-1 is localized on the chromosomes and kinetochore-attached spindle microtubules during metaphase in the smaller, posterior cell (*right*). It is presumed to monitor chromosome attachment and tension. The larger, anterior cell (*left*) has already entered anaphase, and CeBUB-1 is no longer detectable on the chromosomes or spindle microtubules. Thus asynchrony of this second cell cycle in the *C. elegans* embryo allows the observation of both the presence of a functional spindle checkpoint protein during metaphase and its absence after initiation of anaphase. [Encanada et al., 2005, *Mol. Biol. Cell* **16**:1056.]

Proper control of cell division is vital to all organisms. In unicellular organisms, cell division must be balanced with cell growth so that cell size is properly maintained. If several divisions occur before parental cells have reached the proper size, daughter cells eventually become too small to be viable. If cells grow too large before cell division, the cells function improperly and the number of cells increases slowly. In developing multicellular organisms, the replication of each cell must be precisely controlled and timed to faithfully and reproducibly complete the developmental program in every individual. Each type of cell in every tissue must control its replication precisely for normal development of complex organs such as the brain or the kidney. In a normal adult, cells divide only when and where they are needed. However, loss of normal controls on cell replication is the fundamental defect in cancer, an all-too-familiar disease that kills one in every six people in the developed world (see Chapter 24). The

The Eukaryotic Cell Cycle

molecular mechanisms regulating eukaryotic cell division discussed in this chapter have gone a long way in explaining how replication control goes awry in cancer cells. Appropriately, Leland Hartwell, Tim Hunt, and Paul Nurse were awarded the Nobel Prize in Physiology or Medicine in 2001 for the initial experiments that elucidated the master regulators of cell division in all eukaryotes.

The term **cell cycle** refers to the ordered series of events that lead to cell division and the production of two daughter cells, each containing chromosomes identical to those of the parental cell. Two main molecular processes take place during the cell cycle, with resting intervals in between: during the S phase of the cycle, each parental chromosome is duplicated to form two identical sister chromatids; in mitosis (M phase), the resulting sister chromatids are distributed to each daughter cell (Figure 19-1). Chromosome replication and segregation to daughter cells must occur in the proper order

OVERVIEW ANIMATION: Cell Cycle Control

FIGURE 19-1 The fate of a single parental chromosome throughout the eukaryotic cell cycle. Following mitosis (M), daughter cells contain $2n$ chromosomes in diploid organisms and $1n$ chromosomes in haploid organisms. In proliferating cells, G_1 is the period between the “birth” of a cell following mitosis and the initiation of DNA synthesis, which marks the beginning of the S phase. At the end of the S phase, cells enter G_2 containing twice the number of chromosomes as G_1 cells ($4n$ in diploid organisms, $2n$ in haploid organisms). The end of G_2 is marked by the onset of mitosis, during which numerous events leading to cell division occur. The G_1 , S, and G_2 phases are collectively referred to as *interphase*, the period between one mitosis and the next. Most nonproliferating cells in vertebrates leave the cell cycle in G_1 , entering the G_0 state. Although chromosomes condense only during mitosis, here they are shown in condensed form throughout the cell cycle to emphasize the number of chromosomes at each stage. For simplicity, the nuclear envelope is not depicted.

in every cell division. If a cell undergoes chromosome segregation before the replication of all chromosomes has been completed, at least one daughter cell will lose genetic information. Likewise, if a second round of replication occurs in one region of a chromosome before cell division occurs, the genes encoded in that region are increased in number out of proportion to other genes, a phenomenon that often leads to an imbalance of gene expression that is incompatible with viability.

High accuracy and fidelity are required to ensure that DNA replication is carried out correctly and that each daughter cell inherits the correct number of each chromosome. To achieve this, cell division is controlled by surveillance mechanisms known as **checkpoint pathways** that prevent initiation of each step in cell division until earlier steps on which it depends have been completed and mistakes that occurred during the process have been corrected. Mutations that inactivate or alter the normal operation of these checkpoint pathways contribute to the generation of cancer cells because they result in chromosomal rearrangements and abnormal numbers of chromosomes, which lead to further mutations and changes in gene expression level that cause uncontrolled cell growth (see Chapter 24).

In the late 1980s, it became clear that the molecular processes regulating the two key events in the cell cycle—chromosome replication and segregation—are fundamentally similar in all eukaryotic cells. Initially, it was surprising to many researchers that cells as diverse as budding yeast and developing human neurons use nearly identical proteins to regulate their division. However, like transcription

and protein synthesis, control of cell division appears to be a fundamental cellular process that evolved and was largely optimized early in eukaryotic evolution. Because of this similarity, research with diverse organisms, each with its own particular experimental advantages, has contributed to a growing understanding of how cell cycle events are coordinated and controlled. Biochemical, genetic, imaging, and micromanipulation techniques all have been employed in studying various aspects of the eukaryotic cell cycle. These studies have revealed that cell division is controlled primarily by regulating the timing of entry into the cell division cycle, nuclear DNA replication, and mitosis.

The master controllers of the cell cycle are a small number of *heterodimeric protein kinases* that contain a regulatory subunit (**cyclin**) and a catalytic subunit (**cyclin-dependent kinase**, or **CDK**). These heterodimeric kinases regulate the activities of multiple proteins involved in entry into the cell cycle, DNA replication, and mitosis by phosphorylating them at specific regulatory sites, activating some and inhibiting others to coordinate their activities. Regulated degradation of proteins also plays a prominent role in important cell cycle transitions. Since protein degradation is irreversible, this ensures that the processes move in only one direction through the cell cycle.

In this chapter, we first present an overview of the cell cycle and then describe the various experimental systems that contributed to our current understanding of it. We will then discuss cyclin-dependent kinases (CDKs) and the many different ways these key cell cycle controllers can be regulated. Next, we'll examine each cell cycle phase in greater detail

with an emphasis on how control of CDK activity governs the events that take place in each phase. We will then discuss the system of checkpoint pathways that establish the order of the cell cycle and ensure that each cell cycle phase occurs with accuracy. In our discussion we will emphasize the general principles governing cell cycle progression and will use a species-spanning nomenclature when discussing the factors controlling each cell cycle phase. The chapter concludes with a discussion of meiosis, a special type of cell division that generates haploid germ cells (egg and sperm), and the molecular mechanisms that distinguish it from mitosis.

19.1 Overview of the Cell Cycle and Its Control

We begin our discussion by reviewing the stages of the eukaryotic cell cycle, presenting a summary of the current model of how the cycle is regulated. We will see how DNA replication leads to the creation of two identical DNA molecules during the DNA synthesis phase and how these DNA molecules are compacted and structured for their segregation into daughter cells. We will then introduce the master regulators of the cell cycle, the cyclin-dependent kinases, before concluding with an overview of the principles that govern the cell cycle to ensure that the process occurs in the correct temporal fashion and without mistakes.

The Cell Cycle Is an Ordered Series of Events Leading to Cell Replication

As illustrated in Figure 19-1, the cell cycle is divided into four major phases. Cycling (replicating) mammalian somatic cells grow in size and synthesize RNAs and proteins required for DNA synthesis during the G_1 (first gap) phase. When cells have reached the appropriate size and have synthesized the required proteins, they enter the cell cycle by traversing a point in G_1 known as **START**. Once this point has been crossed, cells are committed to cell division. The first step toward successful cell division is entry into the **S (synthesis) phase**, the period in which cells actively replicate their chromosomes. After progressing through a second gap phase, the G_2 phase, cells begin the complicated process of mitosis, also called the **M (mitotic) phase**, which is divided into several stages (Figure 19-2).

In discussing mitosis, we commonly use the term **chromosome** for the *replicated* structures that condense and become visible in the light microscope during the early stages of mitosis. Thus each chromosome is composed of two identical DNA molecules resulting from DNA replication, plus the histones and other chromosome-associated proteins (see Figure 6-39). The two identical DNA molecules and associated chromosomal proteins that form one chromosome are called **sister chromatids**. Sister chromatids are attached to each other by protein cross-links along their lengths.

FOCUS ANIMATION: Mitosis VIDEO: Visualizing Mitosis with Fluorescent Probes

FIGURE 19-2 The stages of mitosis.

During prophase, the nuclear envelope breaks down, microtubules form the mitotic spindle apparatus, and chromosomes condense. At metaphase, attachment of chromosomes to microtubules via their kinetochores is complete. During anaphase, microtubule motors and shortening of spindle microtubules pull the sister chromatids toward opposite spindle poles. After chromosome movement to the spindle poles, chromosomes decondense, and cells reassemble nuclear membranes around the daughter-cell nuclei and undergo cytokinesis.

During **interphase**, the part of the cell cycle between the end of one M phase and the beginning of the next, the outer nuclear membrane is continuous with the endoplasmic reticulum. With the onset of mitosis in **prophase**, the nuclear envelope retracts into the endoplasmic reticulum in most cells from higher eukaryotes, and Golgi membranes break down into vesicles. This is necessary so that the microtubules, nucleated by the **centrosomes**, can interact with the chromosomes to form the **mitotic spindle**, consisting of a football-shaped bundle of microtubules with a star-shaped cluster of microtubules radiating from each end, or spindle pole. A multiprotein complex, the **kinetochore**, assembles at each **centromere**. After nuclear envelope breakdown, the kinetochores of sister chromatids associate with microtubules coming from opposite spindle poles (see Figure 18-37), and chromosomes align in a plane in the center of the cell at **metaphase**. During the **anaphase** period of mitosis, sister chromatids separate. They initially are pulled by microtubules toward the spindle poles and then are further separated as the spindle poles move away from each other (see Figure 19-2).

Once chromosome separation is complete, the mitotic spindle disassembles and chromosomes decondense during **telophase**. The nuclear envelope re-forms around the segregated chromosomes as they decondense. The physical division of the cytoplasm, called **cytokinesis**, yields two daughter cells. Following mitosis, cycling cells enter the G_1 phase, embarking on another turn of the cycle.

The progression of cell cycle stages is the same for all eukaryotes, though the time it takes to complete one turn of the cycle varies considerably between organisms. Rapidly replicating human cells progress through the full cell cycle in about 24 hours: G_1 takes 9 hours; the S phase, 10 hours; G_2 , 4.5 hours; and mitosis, 30 minutes. In contrast, the full cycle takes only 90 minutes in rapidly growing yeast cells. The cell divisions that take place during early embryonic development of the fruit fly *Drosophila melanogaster* are completed in as little as 8 minutes!

In multicellular organisms, most differentiated cells “exit” the cell cycle and survive for days, weeks, or in some cases (e.g., nerve cells and cells of the eye lens) even the lifetime of the organism without dividing again. Such *postmitotic* cells generally exit the cell cycle in G_1 , entering a phase called G_0 (see Figure 19-1). Some G_0 cells can return to the cell cycle and resume replicating; this re-entry is regulated, thereby providing control of cell proliferation.

Cyclin-Dependent Kinases Control the Eukaryotic Cell Cycle

As mentioned in the chapter introduction, passage through the cell cycle is controlled by heterodimeric protein kinases that comprise a catalytic subunit and a regulatory subunit. The concentrations of the catalytic subunits, the **cyclin-dependent kinases (CDKs)**, are constant throughout the cell cycle. However, they have no kinase activity unless they are associated with a regulatory **cyclin** subunit. Each CDK can associate with a small number of different cyclins that determine the substrate

specificity of the complex, that is, which proteins it phosphorylates. Each cyclin is only present and active during the cell cycle stage it promotes and hence restricts the kinase activity of the CDKs it binds to just that cell cycle stage. Cyclin-CDK complexes activate or inhibit hundreds of proteins involved in cell cycle progression by phosphorylating them at specific regulatory sites. Thus proper progression through the cell cycle is governed by activation of the appropriate cyclin-CDK complex at the appropriate time. As we will see, restricting cyclin expression to the appropriate cell cycle stage is one of the many mechanisms cells employ to regulate the activities of each cyclin-CDK heterodimer.

Several Key Principles Govern the Cell Cycle

The goal of each cell division is to generate two daughter cells of identical genetic makeup. To achieve this, *cell cycle events must occur in the proper order*. DNA replication must always precede chromosome segregation. Today we know that the activity of the key proteins that promote cell cycle progression, the CDKs, *fluctuates during the cell cycle*. For example, CDKs that promote S phase are active during S phase but are inactive during mitosis. CDKs that promote mitosis are only active during mitosis. These *oscillations* in CDK activity are a fundamental aspect of eukaryotic cell cycle control, and we have gained some understanding over the last few years as to how these oscillations are generated. Oscillations are generated by **positive feedback mechanisms**, where specific CDKs promote their own activation. These positive feedback loops are coupled to subsequent **negative feedback mechanisms** where, indirectly or with a built-in delay, CDKs promote their own inactivation. Oscillators not only propel the cell cycle forward but also create abrupt transitions between different cell cycle states, which is essential to bring about distinct cell cycle states.

Laid on the cell cycle oscillator machinery is a system of surveillance mechanisms that further ensures that the next cell cycle event is not activated before the preceding one has been completed or before errors that occurred during the preceding step are corrected. These surveillance mechanisms are called **checkpoint pathways**, and their job is to ensure accuracy of the chromosome replication and segregation processes. The system that ensures that chromosomes are segregated accurately is so efficient, a mis-segregation event occurs only once in 10^4 – 10^5 divisions! These multiple layers of control put on the cell cycle control machinery ensure that the cell cycle is robust and error free.

KEY CONCEPTS of Section 19.1

Overview of the Cell Cycle and Its Control

- The eukaryotic cell cycle is divided into four phases: G_1 (the period between mitosis and the initiation of nuclear DNA replication), S (the period of nuclear DNA replication), G_2 (the period between the completion of nuclear DNA replication and mitosis), and M (mitosis).

- Cells commit to a new cell division at a specific point in G_1 known as START.
- Cyclin-CDK complexes, composed of a regulatory cyclin subunit and a catalytic cyclin-dependent kinase (CDK) subunit, drive progression of a cell through the cell cycle.
- Cyclins activate CDKs and are present only in the cell cycle stage that they promote.
- CDK activities oscillate during the cell cycle. Positive and negative feedback loops drive these oscillations.
- Surveillance mechanisms, called checkpoint pathways, guarantee that each cell cycle step is completed correctly before the next one is initiated.

19.2 Model Organisms and Methods to Study the Cell Cycle

The unraveling of the molecular mechanisms governing cell cycle progression in eukaryotes was remarkably speedy and fueled by the powerful combination of genetic and biochemical approaches. In this section we will discuss several model systems and their contribution to the discovery of the molecular mechanisms of cell division. The three most important systems employed to study the cell cycle are the single-celled yeasts *Saccharomyces cerevisiae* (budding yeast) and *Schizosaccharomyces pombe* (fission yeast) and oocytes and early embryos of the frog *Xenopus laevis*. We will also discuss the fruit fly *Drosophila melanogaster*, which proved extremely powerful in the study of the interplay between cell division and development as well as how the study of mammalian tissue culture cells led to the characterization of cell cycle control in mammals.

The studies of the cell division cycle in many different experimental systems also led to two remarkable discoveries about the general control of the cell cycle. First, complex molecular processes such as initiation of DNA replication and entry into mitosis are all regulated and coordinated by a small number of master cell cycle regulatory proteins. Second, these master regulators and the proteins that control them are highly conserved, so that cell cycle studies in fungi, sea urchins, insects, frogs, and other species are directly applicable to all eukaryotic cells, including human cells.

Budding and Fission Yeast Are Powerful Systems for Genetic Analysis of the Cell Cycle

Budding and fission yeast have proved to be valuable systems for the study of the cell cycle. Although they both belong to the kingdom of fungi, they are only distantly related. Both organisms can exist in the haploid state, carrying only one copy of each chromosome. The fact that these yeasts can exist as haploid cells makes them powerful genetic systems. It is easy to generate mutations that inactivate genes in haploids because there is only one copy of each gene (a diploid

system would require an inactivating mutation in each of the two copies of the gene to render its activity nonfunctional). Haploid yeast can be easily employed to screen or select for mutants with specific defects, such as defects in cell proliferation. Additional advantages of the two systems are the relative ease with which one can manipulate the expression of individual genes, their fully sequenced genomes, and the ease with which they can be cultivated and manipulated so that cultures of yeast cells progress through the cell cycle in a synchronous manner.

Budding yeast cells are ovoid in shape and divide by budding (Figure 19-3a). The bud is the future daughter cell and begins to form concomitant with the initiation of DNA replication and continues to grow throughout the cell cycle (Figure 19-3b). Cell cycle stage can therefore be inferred from the size of the bud, which makes *S. cerevisiae* a useful system for identifying mutants that are blocked at specific steps in the cell cycle. Indeed, it was in this organism that Lee Hartwell and colleagues first identified mutants that were defective in progressing through specific cell cycle stages. Like mammalian cells, the budding yeast cell cycle has a long G_1 phase, and the study of the budding yeast cell cycle shaped our understanding of how the G_1 -S phase transition is controlled.

Fission yeast cells are rod shaped and grow entirely by elongation at their ends (Figure 19-4a). After the completion of mitosis, cytokinesis occurs by the formation of a septum (Figure 19-4b). The molecular mechanisms governing G_2 and entry into mitosis are very similar between fission yeast and metazoan cells, and studies with this organism revealed the molecular events surrounding the G_2 -M phase transition.

Budding and fission yeast are both useful for the isolation of mutants that are blocked at specific steps in the cell cycle or that exhibit altered regulation of the cycle. Since cell cycle progression is essential for viability, scientists isolated conditional mutants that encode proteins that are functional at one temperature but become inactive at a different, often elevated, temperature (e.g., due to protein misfolding at the non-permissive temperature). Mutants arrested at a particular cell cycle stage are easily distinguished from normal dividing cells by microscopic examination. Thus, in both of these yeasts, cells with **temperature-sensitive mutations** causing defects in specific proteins required to progress through the cell cycle were readily isolated (see Figure 5-6). Such cells are called *cdc* (cell division cycle) mutants.

How can one identify which gene is defective in a given *cdc* mutant? The wild-type alleles of recessive temperature-sensitive *cdc* mutant alleles can be isolated readily by transforming haploid mutant cells with a plasmid library prepared from wild-type cells and then plating the transformed cells at the non-permissive temperature (Figure 19-5). Haploid mutant cells cannot form colonies at the non-permissive temperature. However, a transformed mutant cell can grow into a colony if it also contains a plasmid that carries the wild-type allele that complements the recessive mutation; the plasmids bearing the wild-type allele can then be recovered from those cells, allowing the identification of the complementing gene. Because many of the proteins that regulate the cell

FIGURE 19-3 The budding yeast *S. cerevisiae*. (a) Scanning electron micrograph of *S. cerevisiae* cells at various stages of the cell cycle. The larger the bud, which emerges at the end of the G₁ phase, the farther along in the cycle the cell is. (b) Main events in the *S. cerevisiae* cell cycle: Daughter cells are born smaller than mother cells and must grow to a greater extent in G₁ before they are large enough to enter the S phase. START is the point in the cell cycle after which

cells are irreversibly committed to undergoing a cell cycle. G₂ is not well defined in budding yeast and is therefore denoted in parentheses. Note that the nuclear envelope does not disassemble during mitosis in *S. cerevisiae* and other yeasts. The small *S. cerevisiae* chromosomes do not condense sufficiently to be visible by light microscopy. [Part (a) courtesy of E. Schachtbach and I. Herskowitz.]

cycle are highly conserved, human cDNAs cloned into yeast expression vectors often can complement yeast cell cycle mutants, leading to the rapid isolation of human genes encoding cell cycle control proteins. In fact, it was the ability of the human gene encoding CDK1 to complement the growth defects caused by inactivation of fission yeast CDK1 that led to the appreciation of the high degree of conservation that exists among eukaryotic cell cycle regulators.

Frog Oocytes and Early Embryos Facilitate Biochemical Characterization of the Cell Cycle Engine

Biochemical studies require the preparation of cell extracts from many cells. For biochemical studies of the cell cycle, the eggs and early embryos of amphibians and marine invertebrates are particularly suitable. These organisms typi-

cally have large eggs, and fertilization is followed by multiple synchronous cell cycles. By isolating large numbers of eggs from females and fertilizing them simultaneously by addition of sperm (or treating them in ways that mimic fertilization), researchers can obtain extracts from cells at specific points in the cell cycle for analysis of proteins and enzymatic activities.

To understand how *X. laevis* oocytes and eggs can be used for the analysis of cell cycle progression, we must first lay out the events of oocyte maturation, which can be recapitulated in vitro. So far, we discussed mitotic division. Oocytes, however, undergo a meiotic division (see Figure 19-38 for an overview of meiosis). As oocytes develop in the frog ovary, they replicate their DNA and become arrested in G₂ for 8 months, during which time they grow in size to a diameter of 1 mm, stockpiling all the materials needed for the multiple cell divisions of the early embryo. When stimulated by a male, an adult female's ovarian cells secrete the steroid

FIGURE 19-4 The fission yeast *S. pombe*. (a) Scanning electron micrograph of *S. pombe* cells at various stages of the cell cycle. Long cells are about to enter mitosis; short cells have just passed through cytokinesis. (b) Main events in the *S. pombe* cell cycle. START is the

point in the cell cycle after which cells are irreversibly committed to undergoing a cell cycle. As in *S. cerevisiae*, the nuclear envelope does not break down during mitosis. [Part (a) courtesy of N. Hajibagheri.]

EXPERIMENTAL FIGURE 19-5 Wild-type cell division cycle (CDC) genes can be isolated from a *S. cerevisiae* genomic library by functional complementation of *cdc* mutants. Mutant cells with a temperature-sensitive mutation in a CDC gene are transformed with a genomic library prepared from wild-type cells and plated on nutrient agar at the non-permissive temperature (37 °C). Each transformed cell takes up a single plasmid containing one genomic DNA fragment. Most such fragments include genes (e.g., X and Y) that do not encode the defective Cdc protein; transformed cells that take up such fragments do not form colonies at the non-permissive temperature. The rare cell that takes up a plasmid containing the wild-type version of the mutant gene (in this case *CDC28*, a cyclin-dependent kinase) is complemented, allowing the cell to replicate and form a colony at the non-permissive temperature. Plasmid DNA isolated from this colony carries the wild-type *CDC* gene corresponding to the gene that is defective in the mutant cells. The same procedure is used to isolate wild-type *cdc⁺* genes in *S. pombe*. See Figures 5-17 and 5-18 for more detailed illustrations of the construction and screening of a yeast genomic library.

FIGURE 19-6 Progesterone stimulates meiotic maturation of *Xenopus* oocytes. (a) Step 1: Progesterone treatment of G_2 -arrested *Xenopus* oocytes surgically removed from the ovary of an adult female causes the oocytes to enter meiosis I. Two pairs of synapsed homologous chromosomes (blue) connected to meiotic spindle microtubules (green) are shown schematically to represent cells in metaphase of meiosis I. Step 2: Segregation of homologous chromosomes and a highly asymmetrical cell division expels half the chromosomes into a small cell called the *first polar body*. The oocyte immediately commences meiosis II and arrests in metaphase II to yield an egg. Two chromosomes connected to spindle microtubules are shown

schematically to represent egg cells arrested in metaphase of meiosis II. Step 3: Fertilization by sperm releases eggs from their metaphase arrest, allowing them to proceed through anaphase of meiosis II and undergo a second highly asymmetrical cell division that eliminates one chromatid of each chromosome in a second polar body. The resulting haploid female pronucleus fuses with the haploid sperm pronucleus to produce a diploid zygote. Step 4: The zygote undergoes DNA replication and the first mitosis. Step 5: The first mitosis is followed by 11 more synchronous divisions to form a blastula. (b) Micrograph of *Xenopus* eggs. [Part (b) copyright © ISM/Phototake.]

hormone progesterone, which induces the G_2 -arrested oocytes to enter meiosis. As we will see in Section 19.8, meiosis consists of two consecutive chromosome segregation phases known as meiosis I and meiosis II. Progesterone triggers oocytes to undergo meiosis I and progress to the second meiotic metaphase, where they arrest and await fertilization (Figure 19-6). At this stage the cells are called eggs. When fertilized by sperm, the egg nucleus is released from its metaphase II arrest and completes meiosis. The resulting haploid egg nucleus then fuses with the haploid sperm nucleus, producing a diploid zygote nucleus. DNA replication follows, and the first mitotic division of embryogenesis begins. The resulting embryonic cells then proceed through 11 more rapid, synchronous cell cycles, generating a hollow sphere of cells called the blastula. Cell division then slows, and subsequent divisions are non-synchronous, with cells at different positions in the blastula dividing at different times.

The advantage of using *X. laevis* to study factors involved in mitosis is that large numbers of oocytes and eggs can be prepared that are all proceeding synchronously through the cell cycle events that follow progesterone treatment and fertilization. This makes it possible to prepare sufficient amounts of extract for biochemical experiments from cells that were all at the same point in the cell cycle. It was in this system that the cyclin-CDK complexes that trigger mitosis and the oscillatory nature of their activity was first dis-

covered. This activity was called **maturation-promoting factor (MPF)** because of its ability to induce entry into meiosis when injected into G_2 -resting oocytes.

Fruit Flies Reveal the Interplay Between Development and the Cell Cycle

The development of complex tissues often requires specific modifications to the cell cycle. Understanding the interplay between development and cell division is thus crucial if we want to understand how complex organisms are built. *Drosophila melanogaster* has established itself as the premier model system for studying the interplay between development and the cell cycle. Not only does the development of this organism involve several highly unusual cell cycles, the powerful genetic techniques that can be applied to fruit flies facilitated the discovery of genes involved in the developmental control of the cell cycle. The first 13 nuclear divisions of the fertilized *Drosophila* embryo all occur in a common cytoplasm and are rapid cycles of DNA replication and mitosis (with no gap phases), fueled by key cell cycle regulators that were stockpiled in the egg cytoplasm as it matured. These divisions are called the syncytial divisions and occur in unison (Figure 19-7). As maternal stockpiles run out, gap phases are introduced, first G_2 , followed by G_1 . Most cells in the embryo cease to divide at this point, form plasma membranes,

VIDEO: Syncytial Divisions of the *Drosophila* Embryo

FIGURE 19-7 Cell division patterns during the life cycle of *Drosophila melanogaster*. After fertilization, nuclei in the embryo undergo 13 rapid S phase–M phase cycles. These are followed by three divisions that include a G₂ phase. All these nuclear divisions occur within a common cytoplasm and are therefore called the syncytial divisions. During late stages of embryogenesis and throughout larval development (with the exception of the nervous system), cells undergo endocycles. This leads to an increase in cellular ploidy and size and

hence larval growth. In the pupa, during a process called metamorphosis, imaginal disks, the tissues that give rise to the adult organs, undergo mitotic divisions and then differentiate to form adult structures. Several types of divisions are seen in the adult fly. Stem cells undergo mitotic divisions, meiosis gives rise to sperm and egg, and endocycles create polyploid cells in the ovary. [Adapted from Lee and Orr-Weaver, 2003, *Ann. Rev. Genet.* 37:545–578.]

and utilize a specialized cell cycle known as the endocycle. In the endocycle, cells replicate their DNA but do not undergo mitosis. This leads to an increase in gene dosage and fuels increased macromolecule biosynthesis, which allows individual cells to grow in size. Thus the embryo, which has now developed into a crawling larva, grows simply by an increase in cell size and not through cell multiplication. A select number of cells do not share this fate. These cells are in the imaginal disks, the organs that will give rise to the adult fly tissues during metamorphosis. Metamorphosis occurs during the pupa stage and transforms larvae into adult flies. The divisions that give rise to the adult fly are canonical cell cycles leading to the adult fly being a diploid organism.

The Study of Tissue Culture Cells Uncovers Cell Cycle Regulation in Mammals

Cell cycle regulation in human cells is more complex than in other non-mammalian systems. To understand this increased level of complexity and to understand the cell cycle alterations that are the cause of cancer, it is important to study the cell cycle not only in model organisms but also in human cells. Researchers use normal or tumor cells grown in plastic dishes to study the properties of the human cell cycle, a method called tissue culture or cell culture. It is, however, important to note that many of the cell types used to study the human cell cycle themselves have altered cell cycle properties due to genetic alterations that occurred during their culturing or because they were isolated from human tumors. Furthermore, in vitro culture conditions do not resemble those found in the organism and could lead to altered behavior of cells. Although some aspects of mammalian cell division are not recapitulated in cell culture conditions—such as the importance of tissue

organization and developmental signals governing cell cycle control—cell culture systems nevertheless provide critical insights into the mammalian cell's intrinsic mechanisms governing cell division. Researchers also work toward establishing culture systems that more closely resemble the cell architecture in tissues. For example, polymers are currently being developed that allow scientists to grow cells in 3-D culture.

As we will see in Chapter 21, primary human cells and other mammalian cells have a finite life span when cultured in vitro. Normal human cells, for example, divide 25–50 times, but thereafter proliferation slows and eventually stops. This process is called *replicative senescence*. Cells can escape this process and become immortalized, allowing researchers to establish cell lines. Although these cell lines harbor genetic alterations that affect some aspects of cell proliferation, they are nevertheless a useful tool to study cell cycle progression in human cells. These cell lines provide an inexhaustible supply of cells that, as we will see next, can be manipulated to progress through the cell cycle in a synchronous manner, allowing for the analysis of protein levels and enzymatic activity at different stages of the cell cycle.

Researchers Use Multiple Tools to Study the Cell Cycle

The experimental analysis of cell cycle properties requires that we are able to determine the cell cycle stage of individual cells. Light microscopy provides some estimate of cell cycle progression. For example, light microscopy allows a researcher to determine whether cultured mammalian cells are in interphase (G₁, S phase, and G₂) or in mitosis. Mammalian tissue culture cells are flat and adhere to the plastic dish during interphase but round up and form spherical structures as they undergo

FIGURE 19-8 Human cells undergoing mitosis. HeLa Kyoto cells were filmed as they underwent mitosis. The images shown were taken every 20 minutes. Cells are flat during interphase, but as cells undergo mitosis, they round up and divide. Subsequently, they flatten out again. [Courtesy of Sejal Vyas and Paul Chang, MIT.]

mitosis (Figure 19-8). Fluorescence microscopy of cellular structures or the analysis of specific cell cycle markers, that is, proteins that are only present in certain cell cycle stages, allows for a more accurate determination of cell cycle stage.

In addition to microscopic tools, cell cycle researchers use flow cytometry to determine the DNA content of a cell population (Figure 19-9; see also Figure 9-2). Cells are treated with a DNA-binding fluorescent dye and the amount of dye that incorporates into the DNA of cells can then be quantitatively assessed using a flow cytometer. Cells are then sorted by their DNA content, and the percentage of cells in G_1 , S phase, and G_2 or mitosis can be assessed in this manner. Cells in G_1 will have half as much DNA as cells in G_2 or mitosis. Cells undergoing DNA synthesis in S phase will have an intermediate amount of DNA.

To characterize different cell cycle events, it is essential to examine cell populations that progress through the cell cycle in unison. Researchers achieve this by *reversibly arresting* cells in

a particular cell cycle stage. This cell cycle arrest is usually accomplished by restricting nutrients or adding anti-growth factors, which cause cells to arrest in G_1 . In budding yeast, for example, cells treated with a mating pheromone arrest in G_1 . When the pheromone is removed from cells (usually by washing them extensively), cells exit the G_1 arrest and progress through the cell cycle in a synchronous manner. In mammalian cells, removal of growth factors by removing serum from the culture medium (serum starvation) arrests cells in G_0 . Re-addition of serum allows cells to re-enter the cell cycle. Other methods involve blocking a certain cell cycle step with chemicals. Hydroxyurea inhibits DNA replication, leading to an S phase arrest. On removal of the drug, cells will resume DNA synthesis in unison. Nocodazole disrupts the mitotic spindle and halts the cell cycle in mitosis. Once the drug is washed away, cells will resume progression through mitosis in a synchronous manner. In budding and fission yeast, the conditional cell division cycle (*cdc*) mutants introduced earlier have proved a powerful tool for creating synchronous cultures. Temperature-sensitive *cdc* mutants, when incubated at the non-permissive temperature, arrest in a particular cell cycle stage because they are defective in a certain key cell cycle protein. Returning cells to the permissive temperature allows cells to continue with the cell division cycle in a synchronous fashion.

EXPERIMENTAL FIGURE 19-9 Analysis of DNA content by flow cytometry. Haploid yeast cells were grown in culture and stained with propidium iodide, a fluorescent dye that incorporates into DNA. The x axis shows DNA content, the y axis the number of cells. The DNA content analysis shows two predominant populations of cells: cells with unreplicated DNA (1C) and with replicated DNA (2C). The cells between the two peaks represent cells that are in the process of undergoing DNA replication. [Courtesy of Heidi Blank.]

KEY CONCEPTS of Section 19.2

Model Organisms and Methods to Study the Cell Cycle

- The ability to isolate mutants and the powerful genetic tools of budding and fission yeast allowed for the isolation of key factors important for cell cycle regulation.
- Frog eggs and early embryos from synchronously fertilized eggs provide sources of extracts for biochemical studies of cell cycle events and identified the oscillatory nature of cyclin-CDK complexes.
- Fruit flies are a powerful system to investigate the interplay between cell division and the developmental programs responsible for building multicellular organisms.
- Human tissue culture cells are used to study the properties of the mammalian cell cycle.

- The generation of synchronized cell populations through reversibly arresting cells in a particular cell cycle stage allows the researcher to examine the behavior of proteins and cellular processes during the cell cycle.

19.3 Regulation of CDK Activity

In the following sections we describe the current model of eukaryotic cell cycle regulation summarized in Figure 19-10 and present some of the experiments that led to this understanding. As we will see, results obtained with different experimental systems and approaches have provided insights into each of the

transition points in the cell cycle. A key discovery in cell cycle studies was that cyclin-dependent kinases govern progression through the cell cycle. Three key features about these kinases are important to keep in mind throughout this chapter:

- Cyclin-dependent kinases (CDKs) are only active when bound to a regulatory cyclin subunit.
- Different types of cyclin-CDK complexes initiate different events. G_1 CDKs and G_1/S phase CDKs promote entry into the cell cycle, S phase CDKs trigger S phase, and mitotic CDKs initiate the events of mitosis (Figure 19-11).
- Multiple mechanisms are in place to ensure that the different CDKs are only active in the stages of the cell cycle they trigger.

VIDEO: Dynamic Behavior of Mitotic Cyclin in HeLa Cells

FIGURE 19-10 Regulation of cell cycle transitions. Cell cycle transitions are regulated by cyclin-CDK protein kinases, protein phosphatases, and ubiquitin-protein ligases. Here the cell cycle is diagrammed, with the major stages of mitosis shown at the top. In early G_1 , no cyclin-CDKs are active. In mid- G_1 , G_1/S phase CDKs activate transcription of genes required for DNA replication. S phase is initiated by the SCF ubiquitin-protein ligase that ubiquitinylates inhibitors of S phase CDKs, marking them for degradation by proteasomes. The S phase CDKs then activate DNA replication and DNA synthesis commences. Once DNA replication is complete, cells enter G_2 . In late G_2 , mitotic CDKs trigger entry into mitosis. During prophase, the nuclear envelope breaks

down and chromosomes align on the mitotic spindle but they cannot separate until the anaphase-promoting complex (APC/C), a ubiquitin-protein ligase, ubiquitinylates the anaphase inhibitor protein securin, marking it for degradation by proteasomes. This results in degradation of protein complexes linking the sister chromatids and the onset of anaphase as sister chromatids separate. After chromosome movement to the spindle poles, the APC/C ubiquitinylates mitotic cyclins, causing their degradation by proteasomes. The resulting drop in mitotic CDK activity, along with the action of protein phosphatases, results in chromosome decondensation, reassembly of nuclear membranes around the daughter-cell nuclei, and cytokinesis.

FIGURE 19-11 An overview of how CDKs regulate cell cycle progression. Cells harbor different types of CDKs that initiate different events of the cell cycle. Importantly, the CDKs are only active in the stages of the cell cycle they trigger. G_1/S phase CDKs are active at the G_1 -S phase transition to trigger entry into the cell cycle. S phase CDKs are active during S phase and trigger S phase. Mitotic CDKs are active during mitosis and trigger mitosis. A ubiquitin ligase known as the anaphase-promoting complex or cyclosome (APC/C) catalyzes two key cell cycle transitions by ubiquitinating proteins, hence targeting them for degradation. The APC/C initiates anaphase and exit from mitosis.

In this section we will first discuss the properties of CDKs and investigate the structural basis of their activation and regulation. We will then see how cyclins activate CDKs and investigate the multiple regulatory mechanisms that restrict the different cyclins to the appropriate cell cycle stage. We will see that protein degradation plays an essential part in this process. In addition, we will discuss how post-translational modifications to CDKs and inhibitory proteins that directly bind to cyclin-CDK complexes are essential additional control mechanisms in restricting different cyclin-CDK activities to the appropriate cell cycle stage.

Cyclin-Dependent Kinases Are Small Protein Kinases That Require a Regulatory Cyclin Subunit for Their Activity

Cyclin-dependent kinases are a family of small (30–40 kD) serine/threonine kinases. They are not active in the monomeric form but, as mentioned previously, require an activating subunit to be active as a protein kinase. In budding and fission yeast, a single CDK controls progression through the cell cycle. Its activity is specified by cell-cycle-stage-specific cyclin subunits. Mammalian cells contain as many as nine CDKs, with four of them, CDK1, CDK2, CDK4, and CDK6, having clearly been shown to regulate cell cycle progression.

They bind to different types of cyclins and together promote different cell cycle transitions. CDK4 and CDK6 are G_1 CDKs and promote entry into the cell cycle, CDK2 functions as a G_1/S phase and S phase CDK, and CDK1 is the mitotic CDK. For historical reasons, the names of various cyclin-dependent kinases from yeasts and vertebrates differ. Whenever possible, we will use the general terms G_1 , G_1/S phase, S phase, and mitotic CDKs to describe CDKs instead of the species-specific terminology. Table 19-1 lists the different names of the various CDKs and indicates when in the cell cycle they are active.

CDKs are not only regulated by cyclin binding but also by both activating and inhibitory phosphorylation. Together, these regulatory events ensure that CDKs are only active at the appropriate cell cycle stage. The three-dimensional structure of CDKs provides insight into how the activity of these protein kinases is regulated. Unphosphorylated, inactive CDK contains a flexible region, called the *T loop*, that blocks access of protein substrates to the active site where ATP is bound (Figure 19-12a). Steric blocking by the T loop largely explains why free CDK, unbound to cyclin, has little protein kinase activity. Unphosphorylated CDK bound to one of its cyclin partners has minimal but detectable protein kinase activity in vitro, although it may be essentially inactive in vivo. Extensive interactions between the cyclin and

TABLE 19-1 Cyclins and CDKs: Nomenclature and Their Roles in the Mammalian Cell Cycle

CDK	Cyclin	Function	General Name
CDK1	Cyclin A, cyclin B	Mitosis	Mitotic CDKs
CDK2	Cyclin E, cyclin A	Entry into the cell cycle S phase	G_1/S phase CDKs S phase CDKs
CDK4	Cyclin D	G_1 Entry into the cell cycle	G_1 CDKs
CDK6	Cyclin D	G_1 Entry into the cell cycle	G_1 CDKs

(a) Free CDK2

(b) Low-activity cyclin A-CDK2

(c) High-activity cyclin A-CDK2

FIGURE 19-12 Structural models of human CDK2. (a) Free, inactive CDK2 unbound to its cyclin subunit, cyclin A. In free CDK2, the T loop blocks access of protein substrates to the γ phosphate of the bound ATP, shown as a ball-and-stick model. The conformations of the regions highlighted in yellow are altered when CDK is bound to cyclin A. (b) Unphosphorylated, low-activity cyclin A-CDK2 complex. Conformational changes induced by binding of a domain of cyclin A (blue) cause the T loop to pull away from the active site of CDK2 so that substrate proteins can bind. The $\alpha 1$ helix in CDK2, which interacts

extensively with cyclin A, moves several angstroms into the catalytic cleft, repositioning key catalytic side chains required for the phosphoryltransfer reaction. The red ball marks the position of the threonine (Thr-160) whose phosphorylation activates CDKs. (c) Phosphorylated, high-activity cyclin A-CDK2 complex. The conformational changes induced by phosphorylation of the activating threonine (red ball) alter the shape of the substrate-binding surface, greatly increasing the affinity for protein substrates. [Courtesy of P. D. Jeffrey. See A. A. Russo et al., 1996, *Nature Struct. Biol.* 3:696.]

the T loop cause a dramatic shift in the position of the T loop, thereby exposing the CDK active site (Figure 19-12b). As we will see shortly, high activity of the cyclin-CDK complex requires phosphorylation of the activating threonine, in the T loop, causing additional conformational changes in the cyclin-CDK complex that greatly increase its affinity for protein substrates (Figure 19-12c). As a result, the kinase activity of the phosphorylated complex is a hundredfold greater than that of the unphosphorylated complex.

Cyclins Determine the Activity of CDKs

Cyclins are so named because their levels change during the cell cycle. They form a family of proteins that is defined by three key features:

- Cyclins bind to and activate CDKs. The activity and substrate specificity of any given CDK is primarily defined by the particular cyclin to which it is bound.
- Cyclins are only present during the cell cycle stage that they trigger and are absent in other cell cycle stages.
- Cyclins not only regulate a particular cell cycle stage but also set in motion a series of events in preparation for the next cell cycle stage. In this way, they propel the cell cycle forward.

Cyclins are divided into four classes defined by their presence and activity during the cell cycle: G_1 cyclins, G_1/S cyclins, S phase cyclins, and mitotic cyclins (see Table 19-1). The different types of cyclins are quite distinct from each other in protein sequence, but all of them contain a conserved 100 amino acid region known as the cyclin box and possess similar three-dimensional structures.

The G_1 cyclins are the lynchpin in coordinating the cell cycle with extracellular events. Their activity is subject to regulation by signal transduction pathways that sense the presence of growth factors or cell proliferation inhibitory signals. In metazoans, G_1 cyclins are known as cyclin Ds, and they bind to CDK4 and CDK6. G_1 cyclins are unusual in that their levels do not fluctuate in a specific pattern during the cell cycle. Instead, in response to macromolecule biosynthesis and extracellular signals, their levels gradually increase throughout the cell cycle.

The G_1/S cyclins accumulate during late G_1 , reach peak levels when cells enter S phase, and decline during S phase (see Figure 19-11). They are known as cyclin E in metazoans and bind to CDK2. The main function for cyclin E-CDK2 complexes, together with cyclin D-CDK4/6, is to trigger the G_1 -S phase transition. This transition is known as START and is defined as the point at which cells are irreversibly committed to cell division and can no longer return to the G_1 state. In molecular terms, this means that cells initiate DNA replication as well as duplicate their centrosomes, which is the first step in the formation of the mitotic spindle that will be used during mitosis.

S phase cyclins are synthesized concomitantly with G_1 cyclins, but levels remain high throughout S phase and do not decline until early mitosis. Two types of S phase cyclins trigger S phase in metazoans: cyclin E, which can also promote entry into the cell cycle and is therefore also a G_1/S cyclin, and cyclin A. Both cyclins bind CDK2 (see Table 19-1) and are directly responsible for DNA synthesis. As we will see in Section 19.4, these protein kinases phosphorylate proteins that activate DNA helicases and load polymerases onto DNA.

Mitotic cyclins bind CDK1 to promote entry into and progression through mitosis. The metazoan mitotic cyclins

are cyclin A and cyclin B (note cyclin A can also trigger S phase when bound to CDK2). Mitotic cyclin-CDK complexes are synthesized during S phase and G₂, but as we will see shortly, their activities are held in check until DNA synthesis is completed. In Section 19.5, we will see that once activated, mitotic CDKs promote entry into mitosis by phosphorylating and activating hundreds of proteins to promote chromosome segregation and other aspects of mitosis. Their inactivation during anaphase prompts cells to exit mitosis, which involves the disassembly of the mitotic spindle, chromosome decondensation, the re-formation of the nuclear envelope, and eventually cytokinesis.

Mitotic cyclins were the first cyclins to be discovered, and it was their characterization that led to the discovery of the oscillatory nature of the activities that govern cell cycle progression. The experiment that led to their discovery is described at the end of this chapter as a classic experiment in cell biology (see Classic Experiment 19.1, Figure 1).

The fact that cyclins are the rate-limiting proteins in triggering cell cycle transitions was discovered using the embryonic

extract system. Using egg extracts from frogs, researchers showed that mitotic cyclins are sufficient to induce mitosis. Cytoplasmic extracts prepared from unfertilized *Xenopus* eggs contain all the materials (mRNAs and proteins) required for multiple cell cycles. When nuclei prepared from *Xenopus* sperm (sperm nuclei are used in this experiment because they are readily isolated in large numbers) are added to such an egg extract, the nucleus and DNA inside it are induced to behave as if progressing through the cell cycle; that is, they replicate their DNA and then undergo mitosis in the extract. Concomitant with the final stages of mitosis, cyclin levels decline (Figure 19-13a). Researchers wanted to determine whether this protein with its fluctuating levels in fact had the ability to induce mitosis. Because mitotic cyclins appeared to be unstable at the end of mitosis, the researchers reasoned that removing the mRNA from the egg extract would prevent the new synthesis of all unstable proteins in the next cell cycle, including that of the mitotic cyclins (all other stable proteins would still be present in the extract). To do this, they digested all mRNAs with a low concentration of

EXPERIMENTAL FIGURE 19-13 Mitotic cyclins are rate limiting for mitosis. In all cases, mitotic CDK activity and mitotic cyclin concentration were determined at various times after addition of sperm nuclei to a *Xenopus* egg extract treated as indicated in each panel. Microscopic observations determined the occurrence of early mitotic events (blue shading), including chromosome condensation

and nuclear envelope disassembly, and of late events (orange shading), including chromosome decondensation and nuclear envelope reassembly. See text for discussion. [See A. W. Murray et al., 1989, *Nature* 339:275; adapted from A. Murray and T. Hunt, 1993, *The Cell Cycle: An Introduction*, W. H. Freeman and Company.]

RNase, which then was inactivated by addition of a specific inhibitor. This treatment destroys mRNAs without affecting the tRNAs and rRNAs required for protein synthesis. When sperm nuclei were added to the RNase-treated extracts, the nuclei replicated their DNA, but they did not undergo mitosis. Furthermore, mitotic cyclin protein was not detected (Figure 19-13b). Addition of mitotic cyclin mRNA, produced in vitro from cloned mitotic cyclin cDNA, to the RNase-treated egg extract induced mitosis as observed with the untreated egg extract (Figure 19-13c). Since mitotic cyclin is the only newly synthesized protein under these conditions, these results demonstrate that the protein is the only one limiting for entering mitosis. Subsequent studies showed that G₁/S phase cyclins have similar properties. Their expression is sufficient to promote entry into the cell cycle, and therefore all the other proteins needed for cell cycle entry are present in unlimited amounts. It is thus clear that the regulation of cyclin levels is an essential aspect of the eukaryotic cell cycle. As we will see in the following section, cells utilize multiple mechanisms to restrict cyclins to the

appropriate cell cycle stage and to keep them at the right concentration.

Cyclin Levels Are Primarily Regulated by Protein Degradation

Multiple mechanisms ensure that CDKs are active in the right stage of the cell cycle. Table 19-2 lists these key regulators of CDKs. In this section we will discuss how the regulation of cyclin levels is brought about. The timely activation of CDKs depends, in part, on the presence of the appropriate cyclins in the cell cycle stage where they are needed. Transcriptional control of the cyclin subunits is one mechanism that ensures proper temporal expression of the cyclins. In somatic cells and yeast, waves of transcription factor activities help establish waves of cyclin activity. A general principle here is that an earlier wave of transcriptional activity helps produce the factors essential to generate a subsequent transcriptional wave. As we will see in Section 19.4, transcription of the G₁/S phase cyclins is promoted by the E2F transcription factor complex.

TABLE 19-2 Regulators of Cyclin-CDK Activity

Type of Regulator	Function
Kinases and Phosphatases	
CAK kinase	Activates CDKs
Wee1 kinase	Inhibits CDKs
Cdc25 phosphatase	Activates CDKs
Cdc14 phosphatase	Activates Cdh1 to degrade mitotic cyclins
Cdc25A phosphatase	Activates vertebrate S phase CDKs
Cdc25C phosphatase	Activates vertebrate mitotic CDKs
Inhibitory Proteins	
Sic1	Binds and inhibits S phase CDKs
CKIs p27 ^{KIP1} , p57 ^{KIP2} , and p21 ^{CIP}	Bind and inhibit CDKs
INK4	Binds and inhibits G ₁ CDKs
Rb	Binds E2Fs, preventing transcription of multiple cell cycle genes
Ubiquitin-Protein Ligases	
SCF	Degradation of phosphorylated Sic1 or p27 ^{KIP1} to activate S phase CDKs
APC/C + Cdc20	Degradation of securin, initiating anaphase. Induces degradation of B-type cyclins
APC/C + Cdh1	Degradation of B-type cyclins in G ₁ and geminin in metazoans to allow loading of replicative helicases on DNA replication origins

Among the many other genes that E2F transcribes are the transcription factors that will promote the synthesis of mitotic cyclins.

The most important regulatory control that restricts cyclins to the appropriate cell cycle stage is ubiquitin-mediated, proteasome-dependent protein degradation. Because protein degradation is an irreversible process, in the sense that the protein can only be replenished through de novo protein synthesis, this regulatory mechanism is ideal to ensure that the cell cycle engine is driven forward and cells cannot “go backward” in the cell cycle. In other words, once a particular cyclin is degraded, the processes that it activated can no longer take place.

Recall that during ubiquitin-mediated protein degradation, ubiquitin-protein ligases polyubiquitinate substrate proteins, marking them for degradation by the proteasome (see Figure 3-29). Cyclins are degraded through the action of two different ubiquitin-protein ligases, SCF (named after the first letters of its constituents, Skp1, Cullin, F-box proteins) and the **anaphase-promoting complex** or **cyclosome** (abbreviated as **APC/C** in this chapter). SCF controls the G_1 -S phase transition by degrading G_1 /S phase cyclins and, as we will see in detail shortly, CDK inhibitory proteins. The APC/C degrades S phase and mitotic cyclins, thereby promoting the exit from mitosis. APC/C also controls the onset of chromosome segregation at the metaphase-anaphase transition by degrading an anaphase inhibitory protein (discussed in Section 19.6).

The SCF and APC/C are multisubunit ubiquitin ligases that belong to the RING finger family of ubiquitin ligases. Despite the fact that SCF and APC/C belong to the same ubiquitin ligase family, their regulation is quite different. The SCF recognizes its substrates only when they are phosphorylated. The SCF is continuously active throughout the cell cycle, and cell-cycle-regulated phosphorylation of its substrates ensures that they are only degraded at certain stages of the cell cycle. In the case of APC/C-dependent protein degradation, the regulation is reversed. Substrates are recognizable throughout the cell cycle, but the activity of the APC/C is cell cycle regulated. APC/C is activated by phosphorylation at the metaphase-anaphase transition, through the action of mitotic CDKs and other protein kinases. The APC/C is then active throughout the rest of mitosis and during G_1 to promote the degradation of cyclins and other mitotic regulators (see Figure 19-11). Substrate specificity of active, phosphorylated APC/C is determined in part by its association with one of two related substrate-targeting factors called Cdc20 and Cdh1. During anaphase APC/C bound to Cdc20 ubiquitinates proteins that lead to chromosome segregation, while during telophase and G_1 , APC/C-Cdh1 targets different substrates for degradation. The substrates of the APC/C contain recognition motifs. The first to be identified is the **destruction box**. It is found in most S phase and mitotic cyclins. This destruction box is both necessary and sufficient to target proteins for degradation.

Today we know that cyclin degradation at the appropriate cell cycle transition is essential for cell cycle progression. The importance of cyclin degradation was again first demonstrated in frog egg extracts. Recall that the accumulation of mitotic

cyclins not only coincided with entry into mitosis, but its disappearance occurred concomitantly with exit from mitosis. This finding raised the possibility that mitotic cyclin degradation was necessary for cells to exit from mitosis. To test this, researchers added an mRNA encoding a nondegradable mitotic cyclin (lacking the destruction box) to a mixture of RNase-treated *Xenopus* egg extract and sperm nuclei. As shown in Figure 19-13d, entry into mitosis occurred on schedule, but exit from mitosis did not. This experiment demonstrates that mitotic exit requires the degradation of mitotic cyclin. Later studies showed that inhibiting the degradation of other cyclins also severely affected cell cycle progression, indicating that ubiquitin-mediated degradation of cyclins is an essential aspect of the eukaryotic cell cycle.

CDKs Are Regulated by Activating and Inhibitory Phosphorylation

Regulating the levels of cyclins is not the only mechanism that controls CDK activity. Activating and inhibitory phosphorylation events on the CDK subunit itself are essential to control cyclin-CDK activity. Phosphorylation of a threonine residue near the active site of the enzyme is required for CDK activity. This phosphorylation is mediated by the **CDK-activating kinase (CAK)**. In some organisms cyclin binding is a prerequisite for CAK phosphorylation, whereas in others this phosphorylation event occurs prior to cyclin binding. Although the sequence of assembling active CDKs differs between organisms, it is clear that CAK phosphorylation of CDK is not a rate-limiting step in CDK activation. CAK activity is constant throughout the cell cycle and phosphorylates the CDK as soon as a cyclin-CDK complex is formed.

Two inhibitory phosphorylations on CDK play a critical role in controlling CDK activity. In contrast to the CAK-induced activating phosphorylation, these inhibitory phosphorylations are regulated. A highly conserved tyrosine (Y15 in human CDKs) and an adjacent threonine (T14 in humans) are subject to regulated phosphorylation. Both residues are situated in the ATP binding pocket of the CDK, and their phosphorylation most likely interferes with positioning of ATP in the pocket. Changes in the phosphorylation of these sites are essential for the regulation of mitotic CDKs and have also been implicated in the control of G_1 /S and S phase CDKs. As we will see in Section 19.5, a highly conserved kinase called Wee1 brings about this inhibitory phosphorylation, and a highly conserved phosphatase called Cdc25 mediates dephosphorylation.

CDK Inhibitors Control Cyclin-CDK Activity

So far, we have discussed the importance of regulating cyclin protein levels and of CDK phosphorylation in controlling CDK activity. The final layer of control that is of critical importance in the regulation of CDKs is a family of proteins known as **CDK inhibitors**, or **CKIs**, that directly bind to the cyclin-CDK complex and inhibit its activity. As we will see in Section 19.4, these proteins play an especially important

role in the regulation of the G_1 -S phase transition and its integration with extracellular signals. It thus comes as no surprise that the genes encoding these CKIs are often found mutated in human cancers (discussed in Chapter 24).

All eukaryotes harbor CKIs involved in regulating S phase and mitotic CDKs. Although these inhibitors display little sequence similarity, they are all essential to prevent premature activation of S phase and M phase CDKs. Inhibitors of G_1 CDKs play an essential role in mediating a G_1 arrest in response to proliferation inhibitory signals. A class of CKIs called *INK4s* (inhibitors of kinase 4) includes several small, closely related proteins that interact only with the G_1 CDKs. Binding of INK4s to CDK4 and CDK6 blocks their interaction with cyclin D and hence their protein kinase activity. A second class of CKIs found in metazoan cells consists of three proteins—p21^{CIP}, p27^{KIP1}, and p57^{KIP2}. These CKIs inhibit G_1 /S phase CDKs and S phase CDKs and must be degraded before DNA replication can begin. As we will discuss in Section 19.7, p21^{CIP} plays an important role in the response of metazoan cells to DNA damage. CKIs regulating G_1 CDKs play a critical role in preventing tumor formation. For example, both copies of the *INK4* gene, which encodes p16, are found inactivated in a large fraction of human cancers.

Special CDK Alleles Led to the Discovery of CDK Functions

Different CDKs initiate different cell cycle phases by phosphorylating specific proteins. It is now clear that rather than phosphorylating a small number of proteins that in turn

initiate a certain cell cycle stage, CDKs phosphorylate a myriad of substrates, thereby directly initiating all aspects of a given cell cycle phase. Analysis of a small number of substrates has provided examples that show how phosphorylation by mitotic CDKs mediates many of the early events of mitosis: chromosome condensation, formation of the mitotic spindle, and disassembly of the nuclear envelope. We will discuss these events in detail in the sections that follow.

In recent years systematic efforts to identify all CDK substrates have been initiated. The challenge in identifying substrates of a particular kinase is how to distinguish that kinase's phosphorylation events from those carried out by other kinases. A breakthrough in understanding which proteins are targets of CDKs was facilitated by the engineering of a CDK mutant in budding yeast that can utilize an analog of ATP that is not bound by other kinases (Figure 19-14). This ATP analog has a bulky benzyl group attached to N₆ of the adenine, which makes the analog too large to fit into the ATP-binding pocket of wild-type protein kinases. However, the ATP-binding pocket of the mutant CDK was modified to accommodate this large ATP analog. Consequently, only the mutant CDK can utilize this ATP analog as a substrate for transferring its γ phosphate to a protein side chain. When the N₆-benzyl ATP analog with a labeled γ phosphate was incubated with yeast cell extracts containing a recombinant mitotic CDK containing the altered ATP-binding pocket, multiple proteins were labeled. True yeast mitotic CDK substrates could be verified among these potential substrates by treatment of cells expressing the mutant CDK with a similar derivative of another ATP analog that binds the mutant CDK in the same way as the

FIGURE 19-14 ATP analog-dependent CDK mutant. (a) Representation of the ATP-binding and catalytic sites of wild-type *S. cerevisiae* CDK1 (called Cdc28 in budding yeast). Bound ATP and a phenylalanine side chain (purple) in the vicinity of the binding pocket are shown in stick format. (b) Bulky ATP analogs such as those containing a benzyl group bound to the N₆ amino nitrogen are too large to fit into the ATP-binding pocket of wild-type protein kinases and thus cannot be

utilized by them. In the *S. cerevisiae* CDK mutant, the phenylalanine at position 88 is changed to glycine, which lacks a large side chain. The mutant exhibits high protein kinase activity using N₆-(benzyl)ATP. These models of *S. cerevisiae* CDK are based on crystal structures of the PKA kinase domain, which shares extensive homology with the kinase domain of *S. cerevisiae* CDK. [See J. A. Ubersax et al., 2003, *Nature* **425**:859; K. Shah et al., 1997, *Proc. Nat'l. Acad. Sci. USA* **94**:3565.]

N_6 -benzyl ATP analog but that cannot be used for substrate phosphorylation. Because of the bulky benzyl group, it is sterically blocked from binding to all other kinases, consequently inhibiting only the mutant CDK. When cells expressing the mutant CDK were treated with this specific CDK inhibitor, most of the putative mitotic CDK targets identified initially were found in a dephosphorylated state, indicating that these proteins are indeed phosphorylated by the CDK in vivo as well as in vitro. In yeast, this procedure identified most of the known CDK substrates plus more than 150 additional yeast proteins. Similar approaches have also been used in mammalian cells to identify CDK substrates. For example, a hunt for substrates of the S phase CDK cyclin A-CDK2 revealed 180 potential substrates. These are currently being analyzed for their functions in cell cycle processes.

KEY CONCEPTS of Section 19.3

Regulation of CDK Activity

- Cyclin-dependent kinases are activated by cyclin subunits. Their activity is controlled at multiple levels.
- Different cyclin subunits activate CDKs at different cell cycle stages. Cyclins are present only in the cell cycle stages that they promote.
- Protein degradation is the key mechanism responsible for restricting cyclins to the appropriate cell cycle stage. This degradation is mediated by the ubiquitin-proteasome system and the ubiquitin ligases APC/C and SCF.
- Activating and inhibitory phosphorylation on the CDK subunit contributes to the regulation of CDK activity.
- CDK inhibitors (CKIs) inhibit CDK activity by directly binding to the cyclin-CDK complex.
- CDKs initiate every aspect of each cell cycle stage by phosphorylating many different target proteins. Systematic efforts using protein kinases engineered to bind only modified forms of ATP have led to the identification of many of these substrates.

19.4 Commitment to the Cell Cycle and DNA Replication

The previous section described the multiple mechanisms that control the different cyclin-CDK complexes. In this and the following two sections we will now examine each cell cycle stage carefully and discuss how a particular cell cycle stage is induced and controlled. We will examine how cells initiate DNA replication and mitosis and how chromosomes are segregated. We will focus on how cyclin-CDK complexes and other key cell cycle regulators impact each cell cycle phase and examine the mechanisms that coordinate their activities.

This section investigates how cells decide whether or not to undergo cell division and how DNA replication is initiated. The process of cell cycle entry is well understood in

budding yeast, and it was in this organism that the molecular mechanisms underlying this cell cycle transition were initially elucidated. We will therefore first examine the molecular events governing cell cycle entry in budding yeast. We will then investigate the striking similarities between the pathways that govern cell cycle entry in yeast and metazoan cells and discuss the realization that many genes involved in this decision are frequently found mutated in cancer. Next we will see that the decision to enter the cell cycle is influenced by extracellular events and learn about the signaling mechanisms that convey these environmental cues to the cell cycle machinery. Finally, we will discuss the molecular mechanisms that govern initiation of DNA replication. We will describe how degradation of an S phase CKI is essential for this process and discover how CDKs ensure that DNA replication occurs only during S phase and then only once.

Cells Are Irreversibly Committed to Cell Division at a Cell Cycle Point Called START

In most eukaryotic cells, the key decision of whether or not a cell will divide is made at the point of whether or not to enter S phase. In most cases, once a cell has become committed to entering the cell cycle, it must complete it. The budding yeast *Saccharomyces cerevisiae* regulates its proliferation in this manner, and much of our current understanding of the molecular mechanisms controlling entry into the cell cycle originated with genetic studies of *S. cerevisiae*.

When *S. cerevisiae* cells in G_1 have grown sufficiently in size, they begin a program of gene expression that leads to entry into the cell cycle. If G_1 cells are shifted from a rich medium to a medium low in nutrients before they reach a critical size, they remain in G_1 and grow slowly until they are large enough to enter the cell cycle. However, once G_1 cells reach the critical size, they become committed to completing the cell cycle, entering S phase and proceeding through G_2 and mitosis, even if they are shifted to a medium low in nutrients. The point in late G_1 when *S. cerevisiae* cells become irrevocably committed to entering and traversing the entire cell cycle is called **START**.

CDK activity is essential for entry into S phase. This was first realized in budding yeast, where temperature-sensitive mutants in the gene encoding CDK1 arrest in G_1 , failing to form a bud and to initiate DNA replication (CDK1 is the only CDK in the budding yeast genome and is known as CDC28). We now know that a CDK cascade triggers entry into the cell cycle. G_1 CDKs stimulate the formation of G_1/S phase CDKs, which then initiate bud formation, centrosome duplication, and DNA replication. In yeast, the G_1 cyclin gene is called *CLN3* (Figure 19-15a). Its mRNA is produced at a nearly constant level throughout the cell cycle, but its translation is regulated in response to nutrient levels and, as we will see shortly, *CLN3* is a lynchpin in coupling cell cycle entry to nutrient signals. Once sufficient Cln3 is synthesized from its mRNA, Cln3-CDK complexes phosphorylate and inactivate the transcriptional repressor Whi5. Phosphorylation of Whi5 promotes its export out of the nucleus, allowing

FIGURE 19-15 Control of the G_1 -S phase transition (a) In budding yeast, Cln3-CDK activity rises during G_1 and is controlled by nutrient availability. Once sufficiently active, the kinase phosphorylates the transcriptional inhibitor Whi5, promoting its export from the nucleus. This causes the transcription factor complex SBF to induce the transcription of the G_1 /S phase cyclins *CLN1* and *CLN2* and of other genes whose products are needed for DNA replication. G_1 /S phase CDKs further phosphorylate Whi5, promoting further *CLN1* and *CLN2* transcription. Once sufficiently high levels of G_1 /S phase CDKs have been produced, START is traversed. Cells enter the cell cycle: they initiate DNA replication,

bud formation, and spindle pole body duplication. (b) In vertebrates, G_1 -CDK activity rises during G_1 and is stimulated by the presence of growth factors. When signaling from mitogens is sustained, the resulting cyclin D-CDK4/6 complexes begin phosphorylating Rb, releasing some E2F, which stimulates transcription of the genes encoding cyclin E, CDK2, and E2F itself. The cyclin E-CDK2 complexes further phosphorylate Rb, resulting in a positive feedback loop that leads to a rapid rise in the expression and activity of both E2F and cyclin E-CDK2. Once G_1 /S phase CDK is sufficiently high, cells traverse START. They commence DNA replication and centrosome duplication.

the transcription factor complex SBF to induce transcription of the G_1 /S phase cyclin genes *CLN1* and *CLN2* as well as other genes important for DNA replication. Once produced, Cln1/2-CDKs contribute to further Whi5 phosphorylation. This positive feedback loop ensures the rapid accumulation of G_1 /S phase CDKs. Once a critical level of Cln1/2-CDKs is reached, these G_1 /S phase CDKs promote bud formation, entry into S phase, and the duplication of the centrosome (also known as the spindle pole body, which later in the cell cycle will organize the mitotic spindle). This state of G_1 /S phase CDK activity, sufficient to initiate S phase, bud formation, and centrosome duplication, is the molecular definition of START.

The E2F Transcription Factor and Its Regulator Rb Control the G_1 -S Phase Transition in Metazoans

The molecular events governing entry into S phase in mammalian—and in fact all metazoan—cells are remarkably similar to those of budding yeast (Figure 19-15b). G_1 cyclins are present throughout G_1 and are often found to be expressed at increased levels in response to growth factors. In turn, the G_1

CDKs activate members of a small family of related transcription factors, referred to collectively as *E2F transcription factors* (E2Fs). During G_1 , E2Fs are held inactive through their association with the retinoblastoma protein (Rb), and G_1 CDKs activate E2Fs by phosphorylating and inactivating Rb. E2Fs then activate genes encoding many of the proteins involved in DNA synthesis. They also stimulate transcription of genes encoding the G_1 /S phase cyclins and the S phase cyclins. Thus the E2Fs function in late G_1 similarly to the *S. cerevisiae* transcription factor complex SBF.

Key to the regulation of E2F function is the **Rb protein**. When E2Fs are bound to Rb, they function as transcriptional repressors. This is because Rb recruits chromatin-modifying enzymes that promote deacetylation and methylation of specific histone lysines, causing chromatin to assume a condensed, transcriptionally inactive form. Rb was initially identified as the gene mutated in retinoblastoma, a childhood cancer of the retina. Subsequent studies found *RB* to be inactivated in almost all cancer cells either by mutations in both alleles of *RB* or by abnormal regulation of Rb phosphorylation.

Rb protein regulation by G_1 CDKs in mammalian cells is analogous to that of Cln3-CDK regulation of Whi5 in yeast.

Phosphorylation on multiple sites by G_1 CDKs prevents Rb association with E2Fs and promotes its export out of the nucleus. This allows E2Fs to activate transcription of genes required for entry into S phase. Once the expression of genes coding for G_1/S cyclins and CDK are induced by phosphorylation of some of the Rb molecules, the resulting G_1/S phase CDK complexes further phosphorylate Rb in late G_1 . This is one of the principal biochemical events responsible for passage through START. Since E2F also stimulates its own expression and that of the G_1/S cyclin-CDKs, positive cross-regulation of E2F and G_1/S cyclin-CDKs produces a rapid rise of both activities in late G_1 .

As they accumulate, S phase CDKs and mitotic CDKs maintain Rb protein in the phosphorylated state throughout the S, G_2 , and early M phases. After cells complete anaphase and enter early G_1 or G_0 , a fall in all cyclin-CDK activities leads to dephosphorylation of Rb. As a consequence, hypophosphorylated Rb is available to inhibit E2F activity during early G_1 of the next cycle and in G_0 -arrested cells. Thus G_1/S phase CDK activity remains low until cells decide to enter a new cell cycle and G_1 CDKs break the inhibitory grasp of Rb over E2F.

Extracellular Signals Govern Cell Cycle Entry

Whether or not cells enter the cell cycle is influenced by extracellular as well as intracellular signals. Unicellular organisms such as yeast, for example, enter the cell cycle only when they have reached an appropriate size, known as the **critical cell size**. This critical size, in turn, is controlled by nutrients available in the environment. This coordination between cell size and cell cycle entry will be discussed in Section 19.7. Here we restrict our discussion to the fact that G_1 cyclin synthesis is responsive to protein synthesis rate, which is in turn controlled by pathways that are regulated by nutrients in the environment. This link between the macromolecule biosynthesis and cell cycle machinery is best understood in budding yeast. In this organism, the G_1 cyclin transcript *CLN3* contains a short upstream open-reading frame that inhibits translation initiation at the *Cln3* open reading frame when nutrients are limited. This inhibition is diminished when nutrients are in abundance. In the presence of sufficient nutrients, the TOR pathway, which senses nutrients and growth factor signals, is active and the pathway stimulates translational activity (see Figure 8-30). Since *Cln3* is a highly unstable protein, its concentration fluctuates with the translation rate of its mRNA. Consequently, the amount and activity of *Cln3*-CDK complexes, which depend on the concentration of *Cln3* protein, is largely regulated by nutrient levels.

In multicellular organisms, cells are surrounded by nutrients, and as such, usually nutrients are not rate limiting for proliferation. Rather, cell proliferation is controlled by the presence of growth-promoting factors (**mitogens**) and growth inhibitory factors (anti-mitogens) in the cell surroundings. Addition of mitogens to G_0 -arrested mammalian cells induces—as we discussed in Chapter 16—receptor tyrosine-kinase-linked signal transduction pathways that initiate signal transduction

cascades that ultimately influence transcription and cell cycle control. They do so in multiple ways.

Mitogens activate the transcription of multiple genes. Most of these genes fall into one of two classes—*early-response* or *delayed-response* genes—depending on how soon their encoded mRNAs appear. Transcription of early response genes is induced within a few minutes after addition of growth factors by signal transduction cascades that activate preexisting transcription factors in the cytosol or nucleus (see Chapter 16). Many of the early-response genes encode transcription factors, such as c-Fos and c-Jun, that stimulate transcription of the delayed response genes. The early response transcription factors AP-1 and Myc induce the transcription of genes encoding G_1 cyclins and CDKs. In addition to being controlled by transcription of the genes encoding the G_1 cyclins, G_1 CDKs are regulated by CKIs. The CKI p15INK4b is a potent CDK inhibitor. In some tissues mitogens inhibit the production of this CKI by inhibiting its transcription.

Cell proliferation in many tissues is not only regulated by proliferation promoting mitogens but also by anti-mitogens, which prevent entry into the cell cycle. Similarly, during differentiation, cells cease to divide and enter G_0 . Some differentiated cells (e.g., fibroblasts and lymphocytes) can be stimulated to re-enter the cycle and replicate. Many postmitotic differentiated cells, however, never re-enter the cell cycle to replicate again. Anti-mitogens and differentiation pathways prevent the accumulation of G_1 CDKs. They antagonize the production of G_1 cyclins and induce the production of CKIs. Transforming growth factor β (TGF- β) is an important anti-mitogen. This hormone induces a signaling cascade that brings about G_1 arrest by inducing the expression of p15INK4b. As we will see in Chapter 24, the signaling pathways that regulate G_1 CDKs are found mutated in most human cancers.

Degradation of an S Phase CDK Inhibitor Triggers DNA Replication

Entry into S phase is defined by the unwinding of origins of DNA replication. The molecular events leading to this event are best understood in *S. cerevisiae*. G_1/S phase CDKs play an essential role in this process. They turn off the degradation machinery that degrades S phase cyclins during exit from mitosis and G_1 and induce the degradation of a CKI that inhibits S phase CDKs.

One of the important substrates of the G_1/S phase cyclin-CDK complexes is Cdh1. During late anaphase, this substrate targeting factor directs the APC/C to ubiquitinylate substrate proteins including S phase and mitotic cyclins, marking them for proteolysis by proteasomes. The APC/C-Cdh1 remains active throughout G_1 , preventing the premature accumulation of S phase and mitotic cyclins. Phosphorylation of Cdh1 by G_1/S cyclin-CDKs causes it to dissociate from the APC/C complex, inhibiting further ubiquitinylation of S phase and mitotic cyclins during late G_1 (Figure 19-16). This, combined with the induced transcription of S phase cyclins during late G_1 , allows S phase cyclin proteins to accumulate as G_1/S cyclin-CDKs levels rise. Later in the cell cycle, S phase and mitotic CDKs

FIGURE 19-16 Regulation of S phase and mitotic cyclin levels in budding yeast. In late anaphase, the anaphase-promoting complex (APC/C) ubiquitinates S phase and mitotic cyclins. APC/C activity is directed toward mitotic cyclins by a specificity factor, called *Cdh1*. *Cdh1* activity is regulated by phosphorylation. During exit from mitosis and G_1 , the specificity factor is dephosphorylated and active; during S phase and mitosis, *Cdh1* is phosphorylated and dissociates from the APC/C, and the ubiquitin ligase is inactive. The G_1 /S-phase CDKs, which themselves are not APC/C-*Cdh1* substrates, phosphorylate *Cdh1* at the G_1 -S phase transition. A specific phosphatase called *Cdc14* removes the regulatory phosphate from the specificity factor late in anaphase.

take over to maintain *Cdh1* in the phosphorylated and hence inactive state. Only as mitotic CDKs decline and a protein phosphatase known as *Cdc14* is activated are these inhibitory phosphates removed from *Cdh1*, leading to its reactivation. In mammalian cells similar mechanisms are responsible for stabilizing S phase and mitotic cyclins, but the phosphatase involved in dephosphorylation of *Cdh1* has not been identified.

In *S. cerevisiae*, as the S phase cyclin-CDK heterodimers accumulate in late G_1 following the inactivation of APC/C-*Cdh1*, they are immediately inactivated by binding of a CKI called *Sic1* that is expressed late in mitosis and in early G_1 (Figure 19-17). Because *Sic1* specifically inhibits S phase and M phase CDK complexes but has no effect on the G_1 CDK

and G_1 /S phase CDK complexes, it functions as an S phase inhibitor. Initiation of DNA replication occurs when the *Sic1* inhibitor is precipitously degraded following its ubiquitinylation by the SCF ubiquitin-protein ligase.

Degradation of *Sic1* is induced by its phosphorylation by G_1 /S phase CDKs (see Figure 19-17). It must be phosphorylated at at least six sites, which are relatively poor substrates for the G_1 /S phase CDKs, before it is bound sufficiently well by SCF to be ubiquitinated. Multiple, poor G_1 /S phase CDK phosphorylation sites lead to an ultrasensitive, switch-like response in *Sic1* degradation and hence precipitous activation of S phase CDKs (Figure 19-18). If *Sic1* were inactivated following the phosphorylation of a single site, *Sic1* molecules would start to get phosphorylated as soon as the levels of G_1 /S phase CDK activity begin to rise, leading to a gradual decrease in *Sic1* levels. In contrast, when several sites need to be phosphorylated, at low levels of G_1 /S phase CDK activity only a few sites are phosphorylated and *Sic1* is not destroyed. Only when G_1 /S phase CDK levels are high is *Sic1* sufficiently phosphorylated at multiple sites to target it for degradation. Thus *Sic1* degradation occurs only when G_1 /S phase CDK activity has reached its peak and virtually all other G_1 /S phase CDK substrates have been phosphorylated.

Once *Sic1* is degraded, the S phase cyclin-CDK complexes induce DNA replication by, as we will see shortly, phosphorylating several proteins involved in activating the replicative helicases. This mechanism for activating the S phase cyclin-CDK complexes—that is, inhibiting them as the cyclins are synthesized and then precipitously degrading the inhibitor—permits the sudden initiation of replication at large numbers of replication origins. An obvious advantage of proteolysis for controlling passage through this critical point in the cell cycle is that protein degradation is an *irreversible process*, ensuring that cells proceed in one direction through the cycle. The dependence of this event on phosphorylation of multiple poor phosphorylation sites makes the degradation of *Sic1*, and hence the activation of DNA replication, abrupt.

FIGURE 19-17 Control of S phase onset in *S. cerevisiae* by regulated proteolysis of the S phase inhibitor, *Sic1*. The S phase cyclin-CDK complexes begin to accumulate in G_1 but are inhibited by *Sic1*. This inhibition prevents initiation of DNA replication until the cells have completed all G_1 events. G_1 /S phase CDKs assembled in late G_1 phosphorylate *Sic1* at multiple sites (step 1), marking it for

ubiquitinylation by the SCF ubiquitin ligase and subsequent proteasomal degradation (step 2). The active S phase CDKs then trigger initiation of DNA synthesis (step 3) by phosphorylating and recruiting MCM helicase activators to DNA replication origins. [Adapted from R. W. King et al., 1996, *Science* 274:1652.]
